1,2,3 Trichloropropane	< 1	< 3

All values are expressed in parts per billion by volume and are based on a sample volume of 1 mL. Values reported as <1 required extrapolation below sample volumes that were actually tested.

LOD, sample mass producing a peak height equal to a blank plus three standard deviations of the noise; LOQ, the sample mass producing a peak height equal to a blank plus 10 standard deviations of the noise. Reproduced with permission from Mouradian *et al.* (1991).

librium method, the actual sample analysed is an air sample.

Detection limits using an FID were found to be $<10 \mu\text{g L}^{-1}$ for benzene, toluene, ethylbenzene and the xylenes (BTEX compounds). Again, by increasing the injection loop volume, these detection limits could be reduced further. Real samples from ground water obtained near a leaking underground storage tank have been analysed and preliminary comparisons to more established methods made. Full validation of the high speed method has not been carried out.

Table 2 Statistical data for air analysis using reverse-flow sample collection with two different sampling periods

Component	Correlation coefficient	Log-log slope	LOD (p.p.b.)	
			20	110
Benzene	0.993	0.99	26	4.6
<i>n</i> -Heptane	0.997	1.04	37	6.9
Toluene	0.999	1.07	25	4.0
Octane	0.995	1.07	47	8.4
<i>p</i> -Xylene	0.999	1.09	29	4.4

Detection limits (LOD) for a signal-to-noise ratio of 3.0 for both the 20 s and the 110 s sampling times. Reproduced with permission from Akard and Sacks (1994).

An alternative method for aqueous sample analysis combines solid-phase microextraction (SPME) with fast GC. The SPME extraction is conducted on the headspace above a water sample in a sealed vial. The analytes are then rapidly desorbed in a specially made injection port into a commercially available portable gas chromatograph. Separation of the BTEX compounds is achieved in less than 30 s. The photoionization detector for this work was not optimized for fast separations. Modification of the detector internal volume is required to reduce band broadening and provide performance suitable for use with high speed GC without the use of make-up gas. As the headspace above a sample is extracted with the SPME fibre, the method is easily adapted to soil sample analysis for VOCs.

One reason for the lack of published applications dealing with VOC analysis in water may be the large disparity between chromatographic analysis time and sample preparation time. Having a chromatographic time scale of 20 s (Figure 3), as is the case with this

Figure 3 High speed chromatogram of the static headspace above a sample of gasoline-contaminated ground water. Peak identification. 1, methyl *t*-butyl ether ($2370 \mu\text{g L}^{-1}$); 2, benzene ($97 \mu\text{g L}^{-1}$); 3, toluene ($109 \mu\text{g L}^{-1}$); 4, ethylbenzene ($2 \mu\text{g L}^{-1}$); 5, co-eluting *m*- and *p*-xylenes ($12 \mu\text{g L}^{-1}$); 6, *o*-xylene ($<0.3 \mu\text{g L}^{-1}$). (Reproduced with permission from Wang *et al.*, 1991.)

BTEX analysis, has little advantage when the sample preparation time is between 20 and 60 min.

Pesticides

Due to concerns regarding adverse health effects resulting from pesticide residues in food or run-off from fields into the water supply, a large number of analytical methods have been published concerned with pesticide analysis. With the increase in studies linking pesticide residues to adverse human health effects comes a concurrent increase in the number of samples required to be analysed for pesticides.

Several approaches to speeding up pesticide analysis have been taken. One approach utilized the two-dimensional chromatographic approach for a comprehensive analysis of up to 17 pesticides. The two-dimensional approach has the advantage that if the two stationary phases have completely different retention mechanisms for the analytes then a truly orthogonal separation is achieved.

The instrumentation in the two-dimensional approach housed both GC columns (first column $2\text{ m} \times 250\text{ }\mu\text{m}$ i.d., second column $0.80\text{ m} \times 100\text{ }\mu\text{m}$ i.d.) in a single GC oven connected via a home-made thermal desorption modulator. The modulator collects the eluent from the first column and releases it on to the second column with a cycle time of 2.5 s. Thus, analysis in the first dimension is 4 min and 5 s in the second dimension. **Figure 4** shows the chro-

matogram obtained in the first dimension without any separation in the second dimension. Poor peak resolution is clearly seen.

Quantitation is achieved with one of two internal standards (IS). Using a FID, LOD values are between 1.8 and 3.8 pg of pesticide on-column and the relative standard deviation (RSD) of the response (in volume counts pg^{-1}) is less than 10% for all four pesticides reported.

This method has been used for a spiked human serum sample after supercritical fluid extraction. Although one of the IS peaks overlapped with a matrix component, quantitation was still possible using the other IS. This overlap can clearly be seen in **Figure 5**. The method allows for faster method development as rapid feedback on the performance of the extraction process is provided. This has been found to be very useful in this application as the supercritical fluid extraction method used only reliably extracted eight of the pesticides under investigation.

A second approach has been to use high speed GC as a screening tool for chlorinated pesticides in water samples. The rationale here is that many samples may contain pesticide residues at levels below those set as acceptable by regulatory agencies. By using a fast analysis method for screening, the number of samples requiring full analysis is reduced.

Using a conventional high speed GC system employing a cryotrap/thermodesorption system and a short $100\text{ }\mu\text{m}$ i.d. GC column, separation of 10

Figure 4 First-dimension chromatogram of a pesticide mixture. The GC oven was kept at 120°C for 0.3 min and then programmed at $15^{\circ}\text{C min}^{-1}$ to 180°C . The modulator chamber was kept at 150°C isothermal. Peak identification : 1, dicamba; 2, trifluralin; 3, dicloran and phorate; 4, atrazine; 5, fonofos and diazinon; 6, terbufos; 7, alachlor; 8, metalaxyl; 9, malathion; 10, DCPA; 11, captan; 12, folpet. chlorinated pesticides and an IS in under 2 min has been achieved.

The use of the pulsed-discharge detector operated in the electron capture mode gave on-column LOD values between 10 and 50 fg. This is an order of magnitude lower than that reported in previous work with high speed GC and a conventional radioactive electron-capture detector. These low LOD values allow reduced sample preparation and smaller sample volumes to be used prior to analysis.

The use of nonequilibrium solid-phase microextraction as the sample preparation method reduces the sample preparation time to just over 4 min per sample. The sample preparation step actually consists of a 2 min extraction stage and a 2 min desorption stage. LOD values for the complete method range

from 10 to 20 ng L⁻¹, which is below current regulatory levels set by the Environmental Protection Agency in the USA for these chlorinated pesticides in water. Table 3 shows the detection limits obtained with the fast screening method in comparison to other methods and regulatory levels.

Real river water samples spiked and analysed give good agreement between expected and actual values. Figure 6 shows representative chromatograms obtained from spiked water and blank river water samples together with the focusing of septum bleed. RSD values were found to be high (20%). This was attributed to the very short extraction time. Despite this, the method offers a relatively simple way of screening a large number of samples for chlorinated pesticides.

PAHs

The use of high speed GC coupled with filter tape sampling and thermal desorption has been applied to the online assessment of PAHs in a combustion process.

Gas and particulate material are sampled directly from the emission stack using a null-type probe. A

Figure 7 Overview of the sampling and analysis system for online measurement of PAHs in a combustion process. (Reproduced with permission from Munchmeyer *et al.*, 1996.)

dilution method is used to cool the gas stream to below 50°C so that condensation of the PAHs occurs on particulates in the gas stream. These particulates are then retained on a glassfibre filter. **Figure 7** shows the instrumental layout used for this work.

Once sampling is complete the PAHs are desorbed at 300°C by contact with a heated piston. The sample enters a short (1.6 m) metal capillary column, resistively heated, which allows for rapid cycling. The sample is detected using mass spectrometry. Complete separation of all PAH isomers is not achieved, although overlapping peaks of substances with different mass spectra can be resolved by correlation software. With a sample volume of 100 L the LOD values were found to be below the emission limits for carcinogenic compounds such as benzo[*a*]pyrene.

Solvent Purity

The analysis of impurities in high purity solvents is a very difficult task. By utilizing high speed GC instrumentation which has the ability to control the direction of carrier gas flow through the column this analysis can be greatly simplified.

The ability of dual-flow direction instrumentation allows for minor impurities in the solvent to be separated and identified by venting off the solvent peak only. After the majority of the solvent peak has passed off the column and into the detector, the carrier gas flow is reversed with subsequent refocusing of the residue left on the column in the cryotrap at the column head. This residue can then be reinjected.

This is well illustrated in **Figure 8**, which shows both 2-fluorotoluene and octane as impurities in toluene. Even with only 0.53 nL of sample on-column, the 2-fluorotoluene is still almost completely obscured in the

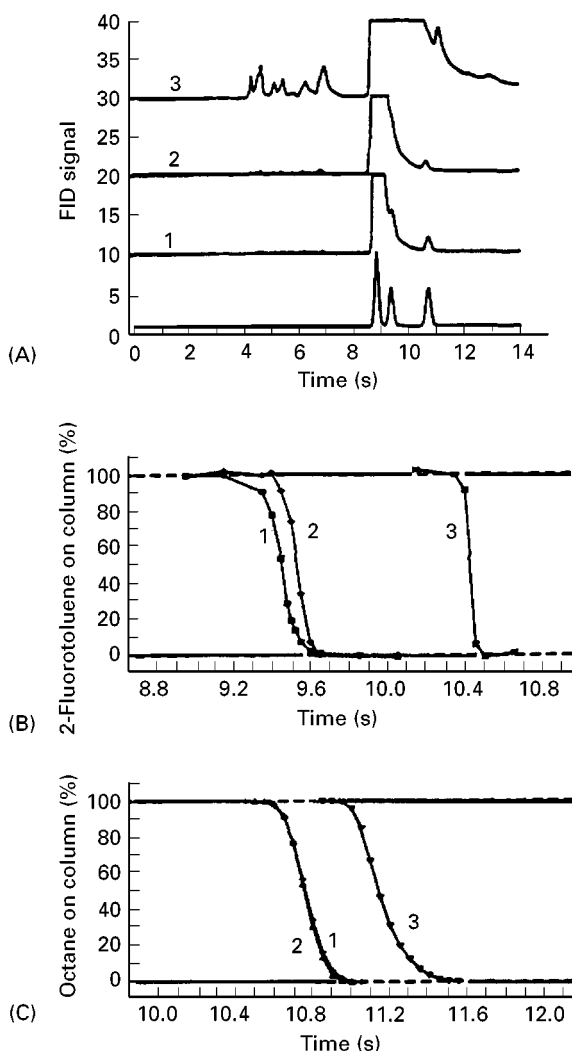

Figure 8 (A) Chromatograms showing the impurities in toluene. For plots 1, 2 and 3, 0.53, 2.67 and 13.3 nL of sample were collected in the cold trap. (B) and (C) show the percentage of impurity on column relative to time before refocusing commenced for plots 1, 2, and 3 from (A). This is the effect of solvent loading on the elution profiles of (B) 2-fluorotoluene and (C) octane in toluene. (Reproduced with permission from Klemp and Sacks, 1991.)

solvent peak. By venting the solvent and refocusing, the impurities can clearly be seen (Part (A), trace 1).

Stationary-phase film thickness is an important consideration in this type of fast analysis. Too thin a film will not sufficiently resolve impurities, which elute prior to the solvent peak. Too thick a film will degrade resolution of the peaks after the solvent peak, increase the size of the solvent tail and increase the total run time. An intermediate film thickness, such as 0.25 μm , is a satisfactory compromise between the two extremes.

Miscellaneous

One novel application of high speed GC has been in the rapid screening of soil gas samples for fuel-related

Figure 9 Comparison of high speed screening mode using the photoionization detector (top) and the advanced field analysis mode using the FID (bottom) for a test mixture containing; A, *n*-pentane; B, benzene; C, toluene; D, ethylbenzene; E, *o*-xylene. (Reproduced with permission from Sacks *et al.*, 1996.)

hydrocarbons. The gas samples are continuously generated from a cone penetrometer (CPT) equipped with a heated probe tip. The GC instrument is located in the CPT truck and connected to a heated gas transport line. The whole instrument is intended to provide high spatial resolution for contaminated soil site characterization.

The instrument can operate in two modes: either a high speed mode to detect BTEX compounds using a photoionization detector, or an advanced field mode using a FID to obtain a finger print-type chromatogram for fuel-type identification. The time frame for the separation in the two modes is 10–20 s and up to 200 s respectively. Figures 9 and 10 show representative chromatograms obtained in the two modes.

Another unusual application has been the coupling of multidimensional high speed GC with Fourier transform infrared (FTIR) detection. Using an offline interface solved the mismatch generated by the fast separation and the slow acquisition of the FTIR

Figure 10 Advanced field analysis chromatograms of headspace from soil samples spiked with diesel fuel. (Top) Sand with 18% moisture; (middle) silty clay with 28% moisture; (bottom) silty loam with 38% moisture. (Reproduced with permission from Sacks *et al.*, 1996.)

Figure 11 Secondary separation: (A) IR reconstructed chromatogram of a segment of a eucalyptus oil separation using a Rtx-1701 column and (B) FID trace. detector. The eluent from the fast GC column was deposited on to a cooled rotating collector disc and actual analysis of the disc with the FTIR was undertaken after completion of the GC run.

The system was applied to the heart-cut analysis of essential oils from cascarilla and eucalyptus. A chromatogram of the eucalyptus analysis is shown

in Figure 11. The use of FTIR detection provides structural information concerning the oil components, even the minor components present. Spectrum quality was found to be sufficient for component identification by library search methods. An infrared spectrum obtained from one of the components in Figure 11 is shown in Figure 12. One disadvantage is

Figure 12 Infrared spectrum of the α -pinene peak (number 3 in Figure 11). The spectra acquisition conditions were 128 scans at 4 cm⁻¹ resolution with a mirror velocity of 1.27 cm s⁻¹. The time for acquiring this spectrum was 120 s. The bands at ~ 3700 and 1600 cm⁻¹ are due to water. (Reproduced with permission from Ragunathan *et al.*, 1994.)

that, for large sample sizes, some decomposition is seen from the reheating of the cryotrap region between the two columns.

Future Developments

High speed GC can probably be best described as currently being in an interim phase. It is in the process of moving from the research laboratory to the analysis laboratory. Most of the basic research demonstrating the feasibility of high speed GC and the instrumental modifications necessary for successful high speed analysis have been accomplished and the findings are well disseminated in the literature, yet the number of true applications remains small.

One technique, which has not been commented on in this article, is the combination of high speed GC with mass spectrometry (MS) as a detection method. The advent of fast scanning time-of-flight mass analysers has provided the data acquisition rates necessary for interfacing with high speed GC. Although the concept of coupling the two techniques together has been demonstrated, no real application articles using both techniques are currently available. Given the prominence of GC-MS analysis in many areas, this will surely change in the near future.

Other future developments will probably include the interfacing of other selective detectors with high speed GC and the subsequent expansion of high speed GC into the areas of analysis served by these selective detectors.

Copyright © 2000 Academic Press

In 1941 Martin and Synge published their classic paper on liquid–liquid partition chromatography in

which they pointed out that there was no reason why the mobile phase should not be a gas. This suggestion was not followed up until 1952 when James and Martin published their paper on the separation of fatty acids by gas–liquid chromatography. This paper generated a frenzy of activity, particularly within the petroleum industry where the method represented an

enormous advance in the separation and analysis of hydrocarbon mixtures. Gas chromatography has now matured into the method of choice for the separation of volatile, thermally stable compounds with an upper molecular weight limit of about 1000 Da and is one of the most widely used laboratory methods today.

The development of gas chromatography was unique in many ways in particular the fact that, although workers in some academic establishments made notable contributions, the major impetus came from industry and from instrument companies. Another factor in its rapid development was the establishment of discussion groups in many countries dedicated to disseminating information on new advances. The Gas Chromatography Discussion Group (now the Chromatographic Society) was established in the UK in 1956 and similar bodies were formed in other parts of Europe and in North America soon afterwards. The history of gas chromatography has been described a number of times; the book by Zlatkis and Ettre gives the reminiscences of some of the early workers.

Four papers are identified in Table 1 that caused major advances in gas chromatography followed by periods of consolidation. These aspects are considered in more detail below.

Column Development

Packed Columns

For many years most gas chromatography was carried out with packed columns. Packed columns for analytical applications have internal diameters usually between 2 and 5 mm and lengths from 0.5 to 5 m, and contain particles around 100–250 μm in diameter with a range of $\pm 25 \mu\text{m}$, carrying the liquid phase. Packed columns have been constructed of various materials but the preferred materials are glass and stainless steel. The packing can be a solid adsorbent such as silica, alumina or graphitized carbon for gas–solid chromatography or a porous support coated with a high boiling liquid for gas–liquid chromatography. The usual support for the liquid phase is diatomaceous earth, a form of naturally occurring silica, with a surface area of about 0.5–4.0 $\text{m}^2 \text{g}^{-1}$ and a capacity to retain physically 5–30% (w/w) of liquid phase. Celite, a commercial diatomaceous earth, was used by Martin and James in their early experiments and is still a common support for packed columns. Polar compounds such as those found in the biomedical field give severe tailing, possible decomposition and

structural rearrangements or even complete adsorption on untreated diatomaceous earth. Acid and/or base washing to remove metallic impurities and silanization of surface silanol groups are widely used to minimize these effects. Fluorocarbon powders have been used occasionally in the separation of reactive compounds such as hydrogen chloride and organo-metallic compounds. Glass beads have also been used in theoretical studies, but have no practical application.

With packed columns the only way to make a radical alteration in the selectivity is by changing the liquid phase. This gave rise to a large number of stationary liquids, many with similar separation properties. Rohrschneider developed an empirical classification method based on the comparison of Retention Index (see below) differences for a number of standard compounds on the liquid phase to be characterized, relative to squalane as a reference phase. The scheme was extended by McReynolds and although it had no fundamental basis it did allow a list of preferred liquid phases to be drawn up. By employing the Rohrschneider-McReynolds classification the number of liquid phases can be drastically reduced and seven phases can be recognized as preferred choices for packed column gas-liquid chromatography (Table 2). If sample volatility is also considered then a poly(dimethylsiloxane) such as OV-1 would have to be substituted for squalane.

Another factor in the move towards rationalization of the choice of stationary phase was the introduction by Kováts in 1958 of the Retention Index system for expressing retention times (or volumes) relative to a series of standards. This was not a new idea, but Kováts proposed that the normal paraffins be taken as the standards for the scale of reference. The Retention Index system took rather a long time to be accepted since it was originally published in an over-complicated form in German and it was not until it was publicized by Ettre in *Analytical Chemistry* some years later that the system received wider acceptance.

Much work has been carried out on the relationship between structure and Retention Index and the concept has proved so useful that it has been transferred in a modified form to liquid chromatography.

Current uses of packed columns include large scale separations, physicochemical measurement of compounds used as stationary phases (inverse gas chromatography), separations employing stationary phases not easily immobilized on fused silica surfaces (see below) and the routine analysis of simple mixtures in a dirty matrix not tolerated by open-tubular columns.

Open-Tubular Columns

In 1958 Golay, wishing to simplify the mathematics of the flow of gas in a packed column with many tortuous paths, used a model consisting of a tube of capillary dimensions. He was able to demonstrate theoretically that such a capillary coated with a thin film of liquid would give columns with very high numbers of theoretical plates. The fundamental difference between packed and open-tubular columns is the much lower resistance to gas flow of the latter, which means that in practice very much longer columns can be used and very high efficiencies obtained. The reason for the need for a column of capillary dimensions can be understood from the equation derived by Golay stated in its modern form:

$$H = \frac{f_1[2D_{m,o}]}{u_o} + \frac{f_1[1 + 6k + 11k^2]d_c^2 u_o}{96(1 + k)^2 D_{m,o}} + \frac{f_2[2k]d_f^2 u_o}{3(1 + k)^2 D_s}$$

Here H is the height equivalent to a theoretical plate, f_1 and f_2 are pressure correction factors, k is the retention factor (frequently called the capacity factor), $D_{m,o}$ is the solute diffusion coefficient in the mobile phase at the column outlet pressure, D_s is the solute diffusion coefficient in the stationary phase, u_o is the velocity of the mobile phase at the column

Table 2 Selection of preferred stationary phases for method development at intermediate column temperatures

Representative phase	Solvent characteristics
Squalane	Low cohesion and minimal capacity for polar interactions
OV-17	Low cohesion with a weak capacity for dipole-type interactions and weak hydrogen-bond basicity
QF-1	Low cohesion and intermediate capacity for dipole-type interactions combined with low hydrogen-bond basicity
U50HB	Low cohesion and weak dipole-type interactions with interactions with intermediate hydrogen-bond basicity
CW 20M	Low cohesion and intermediate capacity for dipole-type interactions and intermediate hydrogen-bond basicity
QTS	Intermediate cohesion with a large capacity for dipole-type interactions and strong hydrogen-bond basicity
OV-275	Very cohesive solvent with a large capacity for dipole-type interactions and intermediate hydrogen-bond basicity

outlet, d_c is the column internal diameter and d_f is the thickness of the film of stationary phase.

The three additive components of the plate height represent the contributions of longitudinal diffusion, resistance to mass transfer in the mobile phase and resistance to mass transfer in the stationary phase, respectively. Open-tubular columns minimize the contribution from resistance to mass transfer in the mobile phase. The stationary phase mass transfer term becomes increasingly important as the liquid film thickness increases beyond about 1 μm .

Soon after his theoretical investigation, Golay was able to demonstrate successfully the practical application of the theory. An important factor in the development of open-tubular (capillary) columns was the discovery of the flame ionization detector capable of giving adequate signals for the small sample sizes required by these columns. These early advances gave some spectacular separations, especially for complex hydrocarbon mixtures, but the general use of open-tubular columns evolved only slowly because many difficult problems remained that required a further 20 years of development. Stainless steel capillaries gave satisfactory performance for hydrocarbon mixtures but for more polar compounds they gave tailing peaks and poor efficiencies, owing to adsorption. Desty and co-workers described a glass-drawing machine capable of producing long lengths of coiled glass capillary tubing as early as 1960 but it was soon found that it was difficult to obtain uniform and stable thin films on glass columns. The surface was too smooth to allow good adhesion by physical adsorption of many of the phases commonly employed at the time, and the many metals included in glass, although at relatively low concentrations, gave rise to adsorption of polar analytes. Considerable effort was expended to overcome these problems, particularly notable being the work of G. and K. Grob. Leaching with aqueous hydrochloric acid to remove some of the surface metal ions followed by treatment with silanes was one approach. Deposition of a layer of barium carbonate to retain the stationary liquid was another practical solution. Such treatments, although successful in skilled hands, were regarded by many as a black art and the resulting columns were fragile and easily destroyed. Figure 1 shows the separation of peppermint oil on three generations of Carbowax 20M columns up to 1980.

In addition to the work on true open-tubular columns, intermediate variants between these and packed columns were developed. These include micro-packed columns and support-coated open-tubular (SCOT) columns where a thin coating of a very fine diatomaceous support was deposited on the inner wall of a stainless steel capillary. Another

Figure 1 Three generations in gas chromatography. Peppermint oil separated on (A) 6 ft \times $\frac{1}{4}$ in. i.d. packed column, (B) 500 ft \times 0.03 in. i.d. stainless steel open-tubular column, and (C) 50 m \times 0.25 mm i.d. glass open-tubular column. All columns contained Carbowax 20 M stationary phase and were operated under optimized conditions. (Reproduced with permission from Jennings W (1979) The use of glass capillary columns for food and essential oil analysis. *Journal of Chromatographic Science* 17: 636–639, Copyright Preston Publication, Inc.)

variant was the porous-layer open-tubular (PLOT) column with a thin coating of an adsorbent on the inner wall of the capillary. PLOT columns still find application for the analysis of low boiling mixtures such as light hydrocarbon gases, but the other types are now no longer used.

The introduction of open-tubular columns made from fused silica in 1979 made glass capillaries obsolete almost overnight and also caused packed columns to be displaced as the dominant type. Currently the dimensions of commercially available open tubular columns range from 100 μm to 530 μm in inner diameter and from 5 m to 100 m in length.

Today nearly all open-tubular columns are prepared from either fused silica or metal capillaries

lined with fused silica. Fused silica is essentially pure silicon dioxide containing less than 1 ppm of metallic impurities. When drawn, these capillaries are very fragile and must be protected from moisture and surface imperfections by the application of an outer coating of a polymer or aluminium layer immediately on production. After such treatment the tubing is rugged and sufficiently flexible to be coiled into a circle of 10 cm diameter or less. Typical performance characteristics of modern wall-coated open-tubular (WCOT) columns are summarized in Table 3 and compared those of classical packed columns.

To achieve a high separation efficiency in any type of open-tubular column it is essential that the stationary phase be deposited as a smooth, thin and homogeneous film that maintains its integrity without forming droplets when the column temperature is varied. Phases showing little variation in viscosity with temperature are preferred for this purpose. Many of the stationary phases developed for packed columns are of limited use for WCOT columns and have been replaced by specially synthesized poly(siloxane)s or poly(ethylene glycol)s.

A great advance in column technology that took place about the same time as the introduction of fused silica columns was the immobilization of phases by reaction with the column wall and crosslinking to form a three-dimensional polymer to further stabilize the poly(siloxane) films without destroying their favourable solute diffusion properties. Thermal condensation of nonpolar and medium polar poly(siloxanes) at high temperature with silanol groups on the fused silica surface results in chemical

bonding of the phase to the surface to give columns suitable for use up to 400–425°C. High polarity phases are more difficult to bond; they require careful surface preparation to avoid film disruption during the bonding process and generally yield columns of lower thermal stability. The general approach for immobilization of stationary phases is by free-radical cross-linking of the polymer chains initiated with peroxides, azo compounds, or γ -radiation. With increasing substitution of methyl by bulky or polar functional groups the difficulty of obtaining complete immobilization increases, and moderately polar poly(siloxane) phases are prepared with various amounts of vinyl, tolyl, or octyl groups that increase the success of the cross-linking reaction. Cross-linking is also important in enabling columns to be prepared with thicker films ($> 0.5 \mu\text{m}$) than was possible with physically adsorbed stationary phases. Immobilization of polar phases remains a problem and so far cross-linking reactions are limited, in the main, to poly(siloxane)s and poly(ethyleneglycol)s, which limits the range of selective phases available for open tubular columns. The development of bonding and immobilization techniques facilitated large volume injection and online interfacing with liquid chromatography and supercritical fluid chromatography (or extraction), which require columns with a stationary phase resistant to solvent stripping.

Instrumentation

The essential elements of instrumentation were developed by the early 1960s, but the advent of the

Table 3 Chromatographic properties of commercially available columns

Column type	Length (m)	Internal diameter (mm)	Film thickness (μm)	Phase ratio ^a	H (mm)	N (column)	N/length
Classical	2	2.16	10% (w/w)	12	0.55	3640	1820
Packed	2	2.16	5% (w/w)	26	0.50	4000	2000
WCOT ^b	30	0.10	0.10	249	0.06	480 000	16 000
	30	0.10	0.25	99	0.08	368 550	12 285

	30	0.32	0.32	249	0.20	150 000	5000
	30	0.32	0.50	159	0.23	131 330	4380
	30	0.32	1.00	79	0.29	102 080	3400
	30	0.32	5.00	15	0.44	68 970	2300
	30	0.53	1.00	132	0.43	70 420	2340
	30	0.53	5.00	26	0.68	43 940	1470

^aPhase ratio = volume of gas phase/volume of liquid phase in the column (columns with a low phase ratio are more retentive).

^bSelecting a WCOT column: narrow-bore thin-film columns are used for high speed gas chromatography; columns with 0.25 and 0.32 mm internal diameters are used for general high performance applications; wide-bore columns with thicker films are used as replacements for packed columns; thin-film columns are employed for the separation of compounds of low volatility; and thick-film columns are used for separating volatile compounds and to obtain maximum sample loadability.

microprocessor has effected a radical change in design and use. Most gas chromatographs now have self-diagnostic software so that faults may be revealed and located. There has also been a revolution in the handling of the data produced (see below).

Column Heating

The column heater is generally a forced-circulation air oven, the temperature of which can be changed in a controlled manner with time for temperature programmed separations. Good temperature control is essential to obtain reproducible retention times. A low thermal mass for the oven is also important since it allows rapid cooling after temperature programming. Air circulation ovens give a very satisfactory performance but they do have some limitations. Liquid thermostat baths were frequently employed in early gas chromatography and are still necessary if extremely accurate temperature control is required, as in theoretical studies.

Sample Introduction

The most common method of sample introduction is by means of a microsyringe through a septum-sealed inlet. Microsyringes are useful for introducing liquid or gas samples, a technique developed by N.H. Ray in 1954. For quantitative work, gases are normally introduced by loop sampling valves, which are highly reproducible and readily automated. Solid samples may be introduced after dissolution in a suitable solvent. Direct introduction of solids is seldom used with open-tubular columns.

The limited sample capacity and low carrier gas flow rates associated with open-tubular columns makes sample introduction much more difficult than for packed columns. A thermostatted flash vaporization chamber in which the evaporated sample is mixed with carrier gas and divided between a stream entering the column (carrier gas flow) and a stream vented to waste (split flow) was the first practical solution to this problem. Split injection discriminates against high boiling compounds (bp > 250°C) owing to selective vaporization. Quantitative analysis of wide boiling range mixtures is difficult, and for the analysis of samples present in a dilute solution detectability is limited by the small amount of sample transferred to the column.

The so-called splitless injection technique was devised to overcome some of the deficiencies of split injection for the analysis of mixtures of compounds in a solvent (such as frequently occurs in environmental studies) through the transfer of relatively large volumes to the column. The gas flow through a splitless injector is relatively low, and the sample is introduced into the column over a comparatively long time

(30–60 s), relying on cold trapping and/or solvent effects to refocus the compounds at the head of the column. The importance of these refocusing mechanisms was not fully understood at first but splitless injection did demonstrate the possibility of performing trace analyses with open-tubular columns. It is also easy in practice to convert an injector from split to splitless operation by the operation of valves and minor hardware modifications.

The programmed-temperature vaporization (PTV) injector overcame many of the problems observed with the hot split and splitless injector. The PTV injector is designed to allow rapid heating and cooling and the sample is introduced at a low temperature. A rapid rise in temperature after introduction ensures rapid volatilization of the highest boiling sample components. The PTV injector may be used in both split and splitless modes and the accuracy and precision approach those obtained by cold on-column injection.

The production of wide-bore silica columns in the early 1980s allowed introduction of the syringe needle directly into the column and the use of immobilized phases eliminated the problem of removal of the stationary phase by large volumes of liquid sample. In cold on-column injection the sample is introduced as a liquid into the column inlet where it is subsequently vaporized. Discrimination based on volatility differences has been virtually eliminated and the risk of sample decomposition minimized. With secondary cooling of the injector, the oven temperature can be kept well above the boiling point of the solvent while maintaining the column inlet at a much lower temperature. This is important for using on-column injection in high temperature gas chromatography. Dirty samples present a problem owing to contamination of the sample introduction zone, which leads to poor chromatography and unreliable quantitation.

Detectors

The thermal conductivity detector (TCD) was used extensively in early work and is still used in a much improved form which makes it compatible with wide-bore open-tubular columns. The relatively poor sensitivity of the early TCD meant that it was largely displaced by the flame ionization detector (FID). The combustion of carbon-containing compounds in a small hydrogen/air diffusion flame produces ions that can be detected by applying a voltage between the flame jet and a collector electrode situated around the flame. The detector has a low dead volume, a high sensitivity for nearly all carbon-containing compounds and an extremely wide linear range of response. As already pointed out, the discovery of the FID played a crucial role in the development of open

tubular columns. The FID is rugged, reliable and relatively insensitive to operating variable so that it is now by far the most widely used of all detectors.

The TCD and the FID are universal detectors; that is, they give a response for all substances. This is not strictly true for the FID since it gives no response for the permanent gases and water (which makes it very suitable for the analysis of aqueous samples). Another universal detector, now becoming much more widely employed, is the mass spectrometer. Coupling to a mass spectrometer (GC-MS) dates almost from the beginning of gas chromatography, but in the early days the practical problems and high cost meant that the combination was confined to a few research laboratories. The advent of the silica open-tubular column, improved designs of mass spectrometers, the availability of computers to handle the large amount of data produced and a considerable reduction in cost have resulted in the GC-MS combination becoming very widely used. The great advantage of the mass spectrometer as a detector is its ability to identify the compounds being separated. It is not quite ideal in this respect since isomers sometimes give almost identical spectra, but techniques such as tandem mass spectrometry (MS-MS) and different methods of ionization can overcome some of these problems. Another advantage is that the mass spectrometer can also be used in a selective mode, often with greatly increased sensitivity.

Fourier transform infrared spectroscopy detectors for gas chromatography are also available; their range of application is not as wide as the GC-MS combination but to some extent they are complementary.

In addition to the universal detectors, a number of selective detectors are commercially available. The nitrogen and phosphorus detector (NPD) is similar in design to a conventional FID but has an electrically heated rubidium-glass bead situated between the flame jet and the collector electrode and (for nitrogen compounds) uses a very small hydrogen flow so that there is a heated plasma in the working zone rather than a flame. This detector is widely used for the analysis of drugs and pesticides in environmental and biological research. Other variants of the FID such as the hydrogen atmosphere FID, which gives a response to some gases, and the O-FID for the selective detection of oxygen-containing compounds, also exist.

The electron-capture detector has an outstandingly high response for polyhalogenated compounds and so has found extensive application in pesticide and environmental analysis. Indeed, the start of the concern for the distribution of compounds such as DDT in the environment can be attributed to the development of this detector in the early 1960s.

Other selective detectors include the microwave plasma emission detector, which can detect a number

of elements simultaneously. The photoionization detector gives a high response for environmentally important compounds such as benzene and vinyl chloride and finds use as a portable field instrument. The flame photometric detector and the chemiluminescence detector have a high response to sulfur and are used extensively in the petroleum industry. Chemiluminescence detection has also been used for the selective determination of nitrosamines in foodstuffs. The Hall detector catalytically decomposes the compounds emerging from the gas chromatography column into simple inorganic gases such as hydrogen chloride (for chlorine) and ammonia (for nitrogen), which are absorbed in a circulating stream of aqueous organic solvent followed by monitoring the electrical conductivity of the solution obtained.

Although selective detectors find extensive application for particular problems they are all more demanding in the control of operating parameters than the FID.

Data Handling

Data handling was originally by purely manual measurement of peak heights. It was recognized that peak area measurement was fundamentally better but areas could be obtained and approximately by measuring the peak height and the width at half height. Such an approach was satisfactory for simple mixtures but was totally impractical for mixtures containing perhaps 100 components in widely differing concentrations. Early integrators consisted of mechanical or electromechanical devices such as the ball and disk integrator and integrating amplifiers, but were very limited in range and speed of response. The mid-1960s saw the introduction of the first generation of electronic integrators and a little later the use of mainframe computers to handle data from a number of instruments simultaneously. The large amounts of data produced by open-tubular columns (especially when coupled to a mass spectrometer) can now be handled by a personal computer. The data can be acquired, manipulated and displayed in real time and can be stored electronically almost indefinitely for record purposes.

Future Developments

Looking to the future, it is reasonable to expect continued evolutionary development. In this context it is interesting to note that several new selective detectors have become available in the last few years. The use of GC-MS will become more widespread as the real cost of such instruments continues to fall and the performance of the mass spectrometry detector shows continuous improvement in sensitivity and resolving power.

The gas chromatograph will develop into a module for more complex analysers for automated sample processing and plant control. The separation time will continue to decrease; in the past there has been limited interest in fast separations but this could change as automated sample processing is developed. Increasing use of coupled techniques such as GC-GC, liquid chromatography-GC, and supercritical fluid chromatography-GC for the separation of complex mixtures will give resolution unachievable by single column operation.

Columns with immobilized phases of a wider range of selectivity than currently exist will be developed. New sorbent (PLOT) columns and hybrid columns with low loadings of liquid phases, special application phases for separating enantiomers and isomers, and columns better able to withstand aqueous samples can be expected.

Ion Mobility Mass Spectrometry

Introduction

J. J. Thompson made the first ion mobility measurements about a century ago. Modern ion mobility spectrometry (IMS), however, was first described in the early 1970s. The development of the electron-capture detector (ECD) had generated much interest with its impressive limits of detection, and this provoked thoughts of an ionization detector with an additional level of specificity that could operate as a stand-alone instrument. IMS was introduced initially as 'plasma chromatography', and sometimes as 'gaseous electrophoresis'. Such terms invited unrealistic comparisons between established separation techniques and IMS, with its modest resolving power. Superficial similarities to time-of-flight-mass spectrometry meant that IMS was also initially considered as an atmospheric pressure mass spectrometer, but poor mass-mobility correlations disproved this view too. Such unrealistic expectations arose from a lack of understanding of the principles of operation. Furthermore such misunderstandings confronted with com-

plex responses and memory effects observed in many investigations at that time resulted in disillusionment with the technique by many. IMS was generally dismissed as something of a curiosity.

By the late 1970s advances in sample handling (especially for trace levels) and better electronics led to renewed interest in IMS. Drift tubes were redesigned with heated components, which reduced memory effects, and sample introduction systems were re-evaluated, helping to avoid instrument overloads and allow quantitative work. Perhaps most importantly, IMS was evaluated on its own capabilities, rather than simply being compared with existing techniques.

The result was the appearance of the military chemical agent monitor (CAM) – a sensitive, highly selective, inexpensive, and fully portable instrument. The CAM also demonstrated that it was possible to produce IMS systems that could enable untrained personnel to make difficult chemical measurements in a hostile environment. The extent of the use of IMS in chemical agent monitoring is large. At the moment IMS instruments are issued at the platoon level across all the armies of the western alliance, thus making IMS arguably the most common trace VOC detection system in current use. Plans are underway to issue CAM devices to all military personnel.

The success of CAM encouraged further developments both at research and commercial levels, which are continuing with new applications and modifications constantly being suggested and investigated. Since the early 1980s the name 'ion mobility spectrometry' has been almost universally adopted, suggesting the analogy with mass spectrometry but emphasizing its unique operational basis.

IMS Theory and Instrumentation

Overview of Components and Signals

Figure 1 shows a generalized representation of an IMS system. Gas is brought into the reaction region, where ions are formed from the constituents of the gas. Ions of a selected polarity are moved down an electrical potential gradient and periodically

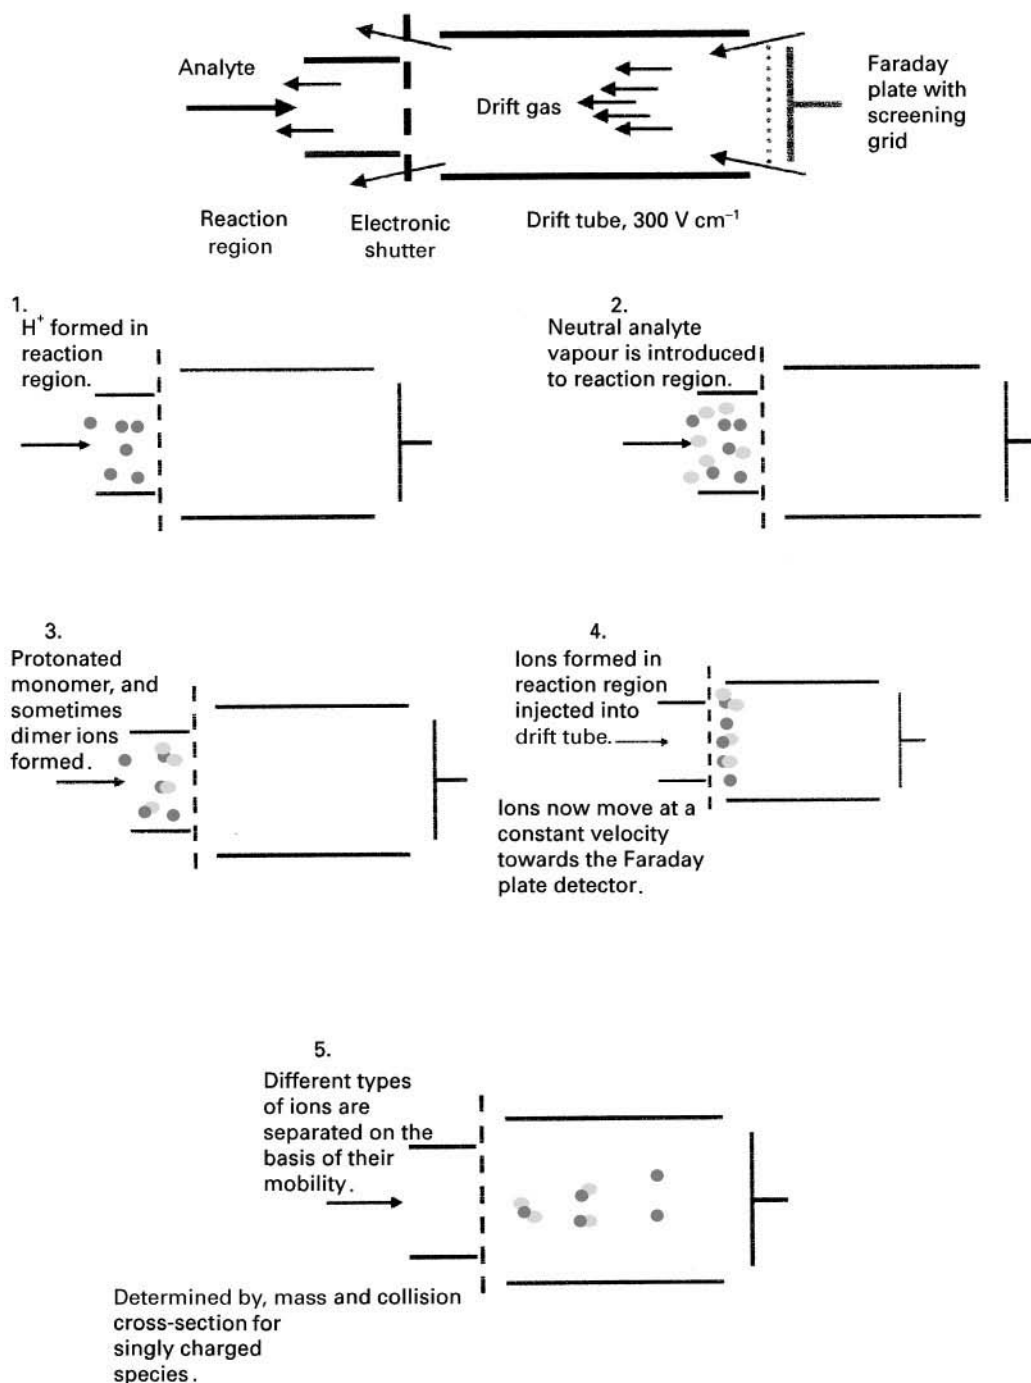

Figure 1 A schematic diagram showing the components and operation of IMS.

introduced into the drift region, where they are accelerated by an electric field and slowed by collisions with a countercurrent drift gas flow. Thus the ions attain an average velocity that is dependent, among other things, on the collision cross-section of the ions in the drift gas, the charge on the ion and its mass (see eqns [15]–[19] below). Consequently, different ions achieve different limiting velocities and thus can be separated. Detection is usually by a Faraday plate, leading to current spikes proportional to the number of ions arriving at different times. The resulting trace is referred to as an ion mobility spectrum.

A single mobility spectrum can be generated in the range of 3 to 25 ms, but the signal-to-noise ratio of the spectrum will be low, and small constituents of the spectrum will often be obscured. Thus, for most applications signal averaging is performed, and typically 1–5 s are required to yield an acceptable spectrum. Mobility spectra (Figure 2) are characterized by the position and area of the peaks produced by the arriving ion packets at the detector. Overall the response can be evaluated in terms of:

- the magnitude of the signal produced by the reactant ions (this is a measure of the amount of charge in the reaction region of the instrument, and the presence of all analytes in the system); and
- the responses associated with a known analyte (by integrating within a given drift time window).

Thus the amount of signal averaging required, and hence the speed of analysis, depends upon which part of the spectrum is relevant to the analysis and the concentrations of analyte in the sample.

Sample Introduction

As IMS is a vapour-phase analysis technique, it is most commonly used with gaseous or volatile

analytes, and analytes are introduced into the reaction region in a carrier gas. This is generally the same gas that is used for the drift flow, and consequently the sample inlet and drift gas flow rates are balanced so that analyte cannot be blown into the drift region.

The direct introduction of ambient air is not normally an effective sample introduction technique as the result is high levels of water and traces of ammonia in the reaction region. The high levels of water in ambient air can lead to formation of cluster ions and thus a loss of resolution in the mobility spectra, while ammonia can dominate the spectrum and prevent analyte response owing to its high proton affinity. Consequently a heated dimethylsilicone membrane is frequently used in the inlet. This excludes excessive amounts of water and ammonia from the reaction region but allows analytes to be sampled. This method works effectively with the military IMS units used for CAM. However, the use of a membrane in the inlet increases the response times of the instrument and reduces the sensitivity.

Not surprisingly, IMS has frequently been used with gas chromatography (GC). In fact the first reports of IMS described GC-IMS systems, and some workers still maintain that IMS cannot be effectively used without chromatography for the sample input. GC has been recognized as intrinsically compatible with IMS, as the carrier gas will not generate a response, samples are typically small enough to avoid saturation of the instrument, and pre-separation of analytes simplifies ionization procedures and responses. Interfacing the techniques is also relatively straightforward, although memory effects were initially found to be a problem. This was overcome by introducing the column effluent either laterally or axially after the ionization source (Figure 3), and allowing it to be carried back through the ionization region by the drift flow. These unidirectional flow configurations reduce IMS cell clearance times and significantly enhance the response of the instrument.

IMS has also been used for liquid samples. Membranes between the liquid sample and a flowing gas stream have enabled IMS to be used to detect chlorinated hydrocarbons and ammonia in water, for example. However, a recent and important development is the coupling of electrospray to IMS. This has been successfully used with IMS to analyse a wide variety of nonvolatile analytes and liquid samples. The electrospray needle is connected into the ionization region instead of the ^{63}Ni source, and the voltages are applied by a power supply independent of the drift voltage supply. Optimization is required in terms of cell and needle temperatures to improve resolution and avoid vaporization of samples before ionization. The electrospray needle is also insulated

Figure 2 A typical mobility spectrum, showing the reactant ion peak (RIP) from clean air and a product ion peak (PIP) from 2,4-lutidine.

Figure 3 Methods for interfacing IMS to gas chromatography. Both these arrangements ensure that clear down times in the reaction region are rapid, while at the same time enabling the efficient production of product ions.

to avoid corona discharges. This coupling has been found to provide stable molecular ions and reproducible well-resolved ion mobility spectra.

Several major applications of IMS involve the detection of nonvolatile analytes at trace levels for example narcotics and explosives. In these applications the analysis of the analytes' headspace would not give a satisfactory response. However, thermal desorption of microparticulates of the analytes into a carrier gas stream and analysis with a heated IMS cell provides a highly sensitive and effective alternative that is the basis of several instrument systems used all over the world in support of police, customs, forensic and airline security applications.

Ionization

Currently, the standard ionization source in IMS instrumentation is ^{63}Ni , favoured because it is stable and places no power demands on a portable instrument. A foil is typically used, often electroplated onto gold or platinum. Ionization principles based on this source are well understood, but there are powerful operational incentives to remove radioactive sources from what are primarily designed as portable instruments. Alternative methods include:

- electrospray ionization;
- photoionization using a UV lamp, which produces no reactant ions and limits the analytes which can be studied;
- laser ionization; and
- corona, with latterly, pulsed corona discharge sources that may be configured to behave in a similar manner to ^{63}Ni .

Currently the development of the pulsed corona discharge source appears to be the most promising alternative to radioactivity for general applications as it consumes little power, lasts a long time, operates in both positive and negative mode, and is already being incorporated into the next generation of miniaturized IMS instruments.

Ionization of the gases in the reaction region is perhaps usefully described in terms of ^{63}Ni , as this is the most widely studied and best-understood ionization source. The first step is direct ionization of the carrier gas by the β -particles emitted by the source, which triggers off a multistage reaction leading to the formation of stable reactant ion species. The following example is for the positive-mode ions in air, or nitrogen with low moisture content:

The dominant positive-mode reactant ions in clean air will thus be $(\text{H}_2\text{O})_n\text{H}^+$, where n will be dependent on the moisture content of the gas as well its pressure and temperature. Minor contributions are also generally seen from $(\text{H}_2\text{O})_n\text{NH}_4^+$ and $(\text{H}_2\text{O})_n\text{NO}^+$.

An analogous reaction scheme occurs for the negative ions, resulting in $(\text{H}_2\text{O})_n\text{O}_2^-$ and some $(\text{H}_2\text{O})_n\text{CO}_4^-$.

When analyte vapours are present in the source region, they may undergo collisional charge transfer reactions with the reactant ions to form product ions in atmospheric pressure chemical ionization (APCI) processes. In almost every case molecular ions are formed in IMS, as APCI causes little fragmentation. Some analyte fragmentation has been observed in IMS, although this has been attributed to thermal decomposition. Typical reaction pathways may be summarized as:

Proton transfer

Cluster formation

Electron capture

Dissociative electron capture

Cluster formation

Proton abstraction

where R is the reactant ion species, P is the product ion species and M is a neutral fragment.

When any of these reactions occur, the mobility spectrum changes, the size of the reactant ion peak (RIP) reduces as the charge reservoir is depleted, and a new peak, the product ion peak (PIP), appears corresponding to the analyte ion (see Figure 2). These peaks will rise and fall in a synergistic relationship, and as charge is conserved in IMS, the summed peak areas of the mobility spectrum should remain constant throughout these changes.

As analyte concentration increases some polar compounds (e.g. esters and alcohols) form a second PIP, observed at longer drift time, which is due to an ion containing two analyte molecules. This is essentially a clustering reaction forming a proton bound dimer:

Dimer formation

A detailed discussion of the formation of proton bound dimers is beyond the scope of this article. Their appearance in a mobility spectrum is a function of the thermodynamics and kinetics associated with their formation along with their stability in the drift tube. The development of proton-bound dimers is usually associated with highly nonlinear responses associated with the monomer form of the PIP (Figure 4).

The formation of product ions occurs rapidly with one or two simple reactions, while the formation of reactant ions is a comparatively slow multi-step process. Once the analyte concentration rises above a critical level the rate of removal of the reactant ions will be faster than their production. This leads to rapid depletion of the charge reservoir in the reactant region, and no further increase in instrument response will be seen. This is referred to as saturation of the instrument, and sets a limit on the response behaviour.

Typical IMS response behaviour with analyte level is shown in Figure 4. The relationship between the instrument response and analyte level for a single-step reaction leading to a product ion may be simply expressed in terms of:

$$\text{RIP}_x = \text{RIP}_0 \times (e^{-\beta x}) \quad [13]$$

$$\text{PIP}_x = \text{RIP}_0 \times (1 - e^{-\beta x}) \quad [14]$$

where RIP_0 is the size of the charge reservoir (RIP peak area in the absence of analyte), RIP_x is the RIP area at analyte concentration x , PIP_x is the PIP area at analyte concentration x , β is the 'reactivity coefficient', a function of reaction time and rate constant and x is the analyte concentration.

Figure 4 Schematic representation of the relationship between analyte concentration and three IMS peaks: R, reactant ions; M, monomer product ion; and D, dimer product ion.

Attempts to fit linear functions to IMS response trends have shown that linearity can only be approximated (with less than 5% errors) over the first 30–40% of the response range. Quantitative work in the literature suggests that the linear dynamic range of IMS is typically between 1 and 2 orders of magnitude of concentration. Beyond this range quantitation is undertaken on the basis of logarithmic relationships. Eventually, once the reactant ions are depleted, the instrument saturates to a population of product ions.

Working at or near saturation should be avoided. Peaks are frequently seen to broaden and/or their mobility vary as excess neutral analyte molecules cluster around the ions (forming new peaks), or further reactions occur in the drift region (broadening and smearing peaks). An excess of neutral analyte within the instrument also often leads to adsorption onto internal surfaces, such that spurious analyte peaks may be seen for a long time after the original analysis.

Proton or electron transfer can only take place if the proton, or electron, affinity of the neutral molecule is greater than that of the reactant ion. In the default case for positive mode air, the proton is held by water, which has a relatively low proton affinity. This suggests a method by which selectivity can be introduced into the ionization process. If a constant supply of suitably high concentration vapour is provided to the reaction region, then all the protons will be captured to form a new population of reactant ions. This is known as ‘doping’ the instrument. A dopant can be chosen to have a proton affinity just below that of the target analyte, so that the required response will still be generated but interferences from all compounds with proton affinity lower than the dopant will be prevented. This method has been successfully applied in many laboratory and field applications and has been found to reduce interferences and simplify responses to mixtures, and in some cases to enhance separation and sensitivity. For example acetone is used to dope CAM units, while nicotinamide is the dopant used for narcotics detection and chlorinated volatile organic compounds are used for explosives doping. However, not all compounds are suitable as dopants, for example pyridine-doped systems respond to all compounds (despite pyridine’s high proton affinity) and give distorted peaks. This is because clustering reactions rather than charge exchange reactions are occurring.

The concentration of dopant has also been found to be important, as too little does not impart full selectivity (i.e. some ‘old’ RIP still remains to react), while too much causes cluster formation due to excess neutrals. When doping conditions are optimized then

often no changes in PIP position or quantitative behaviour are observed between systems with different dopants.

IMS responses to mixtures can become complicated as components in a mixture compete for charge. The distribution of charge between them tends to be on the basis of concentration and ‘reactivity’ (e.g. proton or electron affinity). Thus peak areas for analytes in a mixture will not necessarily quantitatively reflect the proportions of each species present in the reaction region. A further problem with mixtures is that ‘mixed dimer’ ions can be formed, where molecules of two different analytes cluster together around a charge centre. This leads to the appearance of new peaks and more complicated spectra. In these terms the competitive ionization processes can be considered as a source of interferences, in much the same way as overlapping peaks in column chromatography.

In summary, the ionization processes are the cause of some of the major problems of IMS, for example the complicated and congested spectra obtained from mixtures and the limited linear range for many applications. However, they also provide some of the most useful features of the technique such as the spectacular detection limits due to the large number of collisions that occur at atmospheric pressure. Trace levels of analyte are ionized efficiently and the technique is able to respond to a large number of analytes.

Gating the Ions into the Drift Tube

This feature provides IMS with a time-resolved response as opposed to a change in a standing current. An ion shutter is pulsed open for, typically, *c.* 0.2 ms every 5–40 ms, depending on the experimental conditions. The duration that the gate is open is important, as the longer it is open the larger the response (more ions get through) but the broader the ion peaks (greater temporal distribution of identical ions), and hence the lower the resolution will be.

A most important advance has been control of the electric field at the point between the reaction and drift regions with an ion trap. This allows the accumulation of ions between injection pulses rather than their annihilation, with significantly increased sensitivity and much greater control of the ionization processes used to produce the mobility spectra (see Figure 5).

Drift Region and Ion Mobility

The drift region is a region of uniform electric field that moves the ions towards the detector with a flow of drift gas in the opposite direction to the ion

Figure 5 A schematic diagram showing the major systems for ion storage-ion mobility-time-of-flight mass spectrometry.

1. Analytes are ionized and introduced to an ion trap.
2. A tuned ion trap is used to collect ions of a specified mass-to-charge ratio (m/z).
3. The stored ions are injected into a drift tube where they are separated on the basis of their cross-sectional areas.
4. The ions are analysed and quantitated by time-of-flight mass spectrometry.

motion. The drift gas should be inert and free from contaminants, as reactions in the drift region change ion identities and move or broaden peaks. The drift gas also prevents neutrals from the reaction region entering the drift region and undergoing further reactions or clustering.

The electric field is generally provided by a series of conducting field-defining electrodes, and is typically in the range $50\text{--}250\text{ V cm}^{-1}$, which allows weak field approximations to be made with respect to mobility theory, although for many applications it has been shown that the actual value of the electric field is not as important as its homogeneity.

Analytes in IMS are characterized by the drift times of the ions that they form. The mobility of such ions is expressed as:

$$v = \frac{L}{t_d} \quad [15]$$

$$v = KE \quad [16]$$

where v is the ion velocity, L is the drift path length, t_d is the drift time, K is the mobility constant, and E is the electric field strength.

Ion mobility is also dependent on temperature and pressure, so these effects can be accounted for by normalizing to a reduced mobility, K_0 , enabling comparisons to be made between experiments:

$$K_0 = K \left(\frac{273}{T} \right) \left(\frac{P}{760} \right) \quad [17]$$

In practice differences in reduced mobility values are still observed due to variations in the internal instrument parameters used in different instruments. Thus the use of mobility standards has been proposed. Currently, 2,4-lutidine, with a K_0 of

$1.95\text{ cm}^2\text{ V}^{-1}\text{ s}^{-1}$, is widely used as it is considered to be relatively unaffected by temperature, clustering or relative humidity. However, dipropyleneglycol monomethylether ($\text{CH}_3\text{OC}_3\text{H}_6\text{OC}_3\text{H}_6\text{OH}$) has also been proposed for similar reasons. Whatever standard is used, reduced mobility values may be calculated as follows:

$$K_{0(\text{an})} = t_{d(\text{an})} \times \left(\frac{K_{0(\text{std})}}{t_{d(\text{std})}} \right) \quad [18]$$

where (std) refers to values for the standard and (an) refers to values for the analyte under investigation.

The mobility of an ion under weak field conditions is given by:

$$K = \frac{3e}{16N} \times \frac{2\pi^{1/2}}{\mu kT} \times \frac{1}{\Omega} \quad [19]$$

where e is the ion charge, N is the density of neutral molecules (drift gas), μ is the reduced mass of the ion neutral pair $mM/(m+M)$, k is the Boltzmann constant, T is the temperature of the ions and Ω is the collision cross-section.

Detection

The standard detector in IMS instruments is a simple Faraday plate. The vast majority of IMS instruments have an aperture grid placed *c.* 2 mm forward of the detector. While removal of this feature increases the total signal, it also causes broadening of the peaks, typically from *c.* 0.3 ms to *c.* 3 ms, and thus a loss of resolution. The aperture grid prevents incoming ions from inducing a current in the detector plate. Sensitivity may also be increased by increasing the electric field between the aperture grid and detector to a value significantly higher than that of the standard drift field.

The development of new methods and applications for IMS is greatly eased with the use of a mass spectrometer coupled to the drift cell. IMS-MS has been in routine use in research laboratories since the inception of the technique almost 30 years ago. The instruments are interfaced by using a pinhole aperture to the MS vacuum chamber in the Faraday plate of the ion mobility spectrometer. Such a system can be operated in several modes:

- Total ion monitoring yields the full IMS spectrum.
- Opening the shutters provides a full atmospheric pressure chemical ionization mass spectrometric characterization of the ions in the reaction region.
- Selective ion monitoring enables the contribution of specific species to the mobility spectra to be observed.

An exciting and important development has been the introduction of IMS to ion storage mass spectrometry (Figure 5). This combination of instruments has the potential to isolate selectively trace levels of volatile and nonvolatile materials from a wide range of matrices, identify and quantitate them in a time-scale of milliseconds to seconds. The separation speeds reported so far are of the order of greater than 10^6 theoretical plates per minute. Although the approach is still very much in its early stages of development, the potential for vastly increasing the speed of many analyses is considered by many in this field to be a very important factor in the future development of IMS.

Application Areas

Military and Security Applications

The use of IMS to detect chemical warfare agents has already been described. Following on from this application, government research establishments turned their attention to narcotics and explosives. Given the chemical properties of these materials it was not surprising that IMS was found to provide an effective solution to the problem of screening for such materials. Due to the low volatility and trace levels of the substances, these devices use thermal desorption sample introduction systems. The sample is obtained by wiping or vacuuming the surfaces associated with the suspected contamination (for example vehicle interiors, luggage, skin and clothing). Microscopic particles of the analytes are collected onto a filter and thermally desorbed off this medium into the instrument. The devices are installed with a library of spectra and will alarm and identify the substance if a sample produces a matching signal. This method has proven successful at detecting trace levels of a wide range of drugs and explosives materials from a variety of situations, and such devices have become commonplace in airports and at other security checkpoints.

Environmental and Process Monitoring

IMS responds to a vast range of volatile organic compounds as well as inorganic pollutants such as SO_2 , HF, NO_x and H_2S . Adaptations of military technology have been used successfully for applications designed to operate in remote and isolated environments (hydrazine monitoring during space shuttle missions, for example). However, the use of IMS as a presumptive monitoring technique for the supervision of pollution prevention measures has yet to be adopted, although research in Europe and the USA has already begun on the technology transfer from the military to the environmental arena.

IMS has also been applied to water monitoring. Solid-phase extraction, membrane thermal desorption and electrospray of environmental water samples have all been developed. No doubt solid phase micro-extraction will be reported soon as well.

Biological Analytes

The detection and enumeration of bacteria by monitoring for volatiles produced through enzyme-substrate reactions or pyrolysis has been applied to several types of bacteria of water and food hygiene interest (including *Escherichia coli* and *Listeria*). Water, urine and a range of foods have been studied in this way, with significant reduction in analysis times. Given the pedigree of IMS, it is not surprising that aerosol sampling-pyrolysis-GC-IMS systems have been developed for the detection of bacillus spores and other biological warfare agents.

Electrospray-IMS-MS techniques have also been developed for work with biopolymers. These techniques use low-pressure drift tubes (< 10 Torr N_2 , He or Ar) and a relatively weak electric field ($< 50 \text{ V cm}^{-1}$). An ion trap is most commonly used to inject and concentrate the ions. Although a recent development, this approach has already been used to great effect in the study of sequence and structure relationships. Biomolecular separations of complex mixtures, a protease digest for instance, have also been reported with some success. Variation of the potential used for ion injection has been demonstrated to fragment molecules, which enhances isomer identification and suggests a way to provide high speed sequencing information.

Chromatographic Detection

Combined with chromatography IMS provides an additional dimension to the analysis. It can often separate co-eluting components by mobility, the polarity of the drift tube or their proton or electron affinities. Selected drift time monitoring may be used in an exactly analogous way to selected ion monitoring in mass spectroscopy. Indeed, the development of GC-IMS systems by NASA to monitor continuously the air in the International Space Station has shown that GC-IMS has a near equivalent analytical capability to GC-MS – and one that can be achieved with significantly less complexity and cost. Similar developments are underway with HPLC separation, with sub-picogramme detection limits reported for many compounds. This area of activity is undergoing rapid development and it may be that IMS may come to be used as a general-purpose detection system for chromatography.

The Nature of Mobility Data

So far in this discussion the emphasis has been on assigning a feature in an ion mobility spectrum to the products of a specific ion–molecule reaction. However, there are other ways of using the information contained within a mobility spectrum.

It is possible to study gas-phase reactions and ion–molecule processes within the drift tube with a tuned mass spectrometer. Thus, equilibrium constants for clustering reactions, activation energies for ion–molecule reactants and molecular sizes have all been determined with IMS. The introduction of dopant to the drift region of the instrument enables the reaction kinetics of ion–molecule reactions to be studied and data derived so far from such studies have agreed closely with accepted literature values.

IMS data can also be used in a completely phenomenological-based manner. Complex but constant mixtures yield reproducible ion mobility spectra, although the interpretation and assignment of individual features in such spectra is not currently possible. The application of pattern recognition algorithms and standard chemometric tools enables IMS to be used to identify changes in composition or types of sample. So far identification of different types

of polymers, wood species, foodstuffs and pharmaceutical products has been demonstrated. This is an application area that undoubtedly has significant commercial potential.

The Future

Table 1 is a summary of current IMS research areas and applications. The future development of this technique can be seen to fall into three broad areas:

- *The development and improvement of IMS technology.* The problems of instrument saturation, nonlinear responses and complex ambiguous responses are difficult research challenges that will occupy many involved in IMS research and development. New ionization methods and better understanding of the fluid dynamics and kinetics of the ionization process are likely to be important development areas for some time.
- *Sampling interfaces and applications.* Improvements in sampling technology will enable IMS to be exploited in a wider range of contexts. Certainly the successful use of IMS in presumptive testing for narcotics and explosives has interesting possibilities when applied to a wide range of industrial, medical and environmental issues.

Table 1 A summary of current research and application activity in IMS

Analyte	Application area	Comment
Volatile organic compounds (VOC)	Environmental, process, clinical, and forensic analysis Workplace monitoring Chemical agent monitoring Space craft cabin atmosphere monitoring Extra-terrestrial VOC monitoring Kinetic and thermodynamic determinations of ion formations, lifetimes and stabilities	Established areas of operation for IMS. Commercial instruments available that are reliable, rugged and designed for use by the nonspecialist. Recent development offering rapid measurement techniques for characterizing gas-phase reactions. Not yet applied to larger molecules.
Surfaces, bulk materials	Contaminated soil analysis Surface characterization	Laser ablation and desorption techniques, developed recently, have significantly expanded the scope of applications that IMS may be applied to.
Pesticides	Environmental and process analysis	Electrospray ionization has expanded massively the types of analyte and analysis that may now be undertaken with IMS.
Peptides Sugars Proteins DNA and nucleotides	Life sciences Drug discovery Clinical analysis Foodstuffs characterization	Conformer and isomer separations now routinely achievable. Structure elucidation and fast separations of complex mixtures now a possibility.
Bacteria	Food safety Microbiology Biological warfare Clinical analysis	Pyrolysis techniques offer detection limits of 4 to 5 organisms dm ⁻³ , while ELISA approaches are offering fast and highly selective detection methodologies.

- **High speed separations.** The combination of mobility and mass spectrometric technologies described in Figure 5 offers analysis times in the regions of milliseconds to seconds per component. The development of this technology and its application to the life sciences is likely to be a major, perhaps the major, area of IMS development in the medium term. However, the performance of such instrument assemblies has to be offset against their significant capital costs. Miniaturization will play a vital role in this area, reducing the initial outlay required to operate such systems. The work by NASA and the production of GC-IMS databases will continue and it is likely that IMS-based detection systems will become commercially available as alternative approaches to GC-MS.

From the disappointments of the early work with IMS, recent research has yielded substantial advances in this technique. Perhaps the next few years will see the acceptance of IMS as a mainstream analytical approach. Certainly the recent developments in bio-separations have taken many by surprise, and consequently there is a general feeling that the near future will see a huge expansion in the use and application of IMS, particularly in the life sciences.

Large-Scale Gas Chromatography

P. Jusforgues, Prochrom, Champigneulle, France

Copyright © 2000 Academic Press

Introduction

Large scale preparative gas chromatography (GC) is an old established technique: the idea of using a gas chromatographic process to produce pure fractions of a mixture dates back to the 1950s. It took a long time to transform the idea into an efficient and reliable tool for industrial production and, finally, during the 1970s, solutions were found to the crucial problems, and large scale preparative GC became commercially available. At the same time, models were developed to help optimize the separations and to understand the phenomena specific to chromatography at finite concentrations.

The questions raised by large scale preparative GC include the following:

1. What is it?
2. Why is it of interest?

3. How does it work?
4. At what scale?
5. What for (which applications)?
6. How much does it cost?

Principle

Large scale preparative GC uses the same chromatographic principle as analytical GC with packed columns: a carrier gas flows continuously through a column packed with the stationary phase. A pulse of a mixture is injected into the carrier gas at the column inlet and the different components of the mixture are eluted at the column outlet at different times, depending on their volatility and their affinity for the stationary phase. Preparative and analytical GC use the same carrier gases and stationary phases and the same types of detectors.

The goal of preparative GC is not to know the composition of the mixture as in analytical GC but to collect purified fractions for further use. Thus, in large scale preparative GC, for productivity reasons, injected pulses are as large as possible, column

capacity is enlarged (by increasing the diameter) and, at the column outlet, instead of discharging the various fractions to the atmosphere, they are directed to traps where they are condensed and separated from the carrier gas.

Two different categories of preparative GC exist which differ in both size and goal: laboratory-scale preparative GC and large scale preparative GC. Laboratory-scale preparative GC will not be described here since it is very similar to analytical GC. Its goal is to purify milligrams or hundreds of milligrams of compounds in order to identify them further: it is an analytical technique. The equipment used is similar to that used in analytical GC (except for column diameters that can be increased up to 10 mm) and the fraction collector is a simple device in which sample condensation is often not quantitative.

Large scale preparative GC, described below, is made for purification of kilograms and tonnage quantities of compounds.

Interesting Characteristics

The advantage of large scale preparative GC can be described in comparison with other well-known separation techniques such as distillation and liquid chromatography.

Selectivity

The very large selectivity range of packed column analytical GC is also available for preparative GC since the same stationary phases are used. The selectivity is based not only on the difference of volatility of the compounds (as in traditional distillation) but also on their relative affinity for the stationary phase. Thus, the choice of the stationary phase is a powerful tool to customize the separation (e.g. an impurity can be removed from a complex mixture without separating the other compounds).

Another advantage of preparative GC over distillation is the possibility of purifying azeotropic mixtures.

Efficiency

Very high separation efficiencies of several thousand theoretical plates can be obtained in preparative GC; this was one of the key technological points that had to be resolved before process could be commercialized. These high efficiencies allow high purities and/or high productivities of closely related compounds (e.g. *cis-trans* isomers) to be obtained.

Thermal Degradation

A limitation of the applicability of preparative GC is, as for distillation, the degradation of thermolabile

molecules that have to be vaporized. However, one advantage of preparative GC over distillation is the smaller residence time at high temperatures which reduces the thermal degradation.

Flexibility

Associated with the small residence times are the small hold-up volumes (no need for large boilers, no reflux). Thus, the start-up time and stop time of a large unit are smaller than with a large distillation column. It is also easier to clean and to change the application.

Absence of Solvent

The advantage of preparative GC compared with preparative liquid chromatography is its low cost. Indeed, the main drawback of preparative LC is the high cost associated with the large amounts of solvent used. In preparative GC, the equivalent of the solvent is the carrier gas, which is easily separated from the purified sample and can then be recycled at low cost. As a consequence, a large scale GC process costs from 10 to 100 times less than a preparative LC process and the purified sample is collected free of solvent.

Limitations

Despite its advantages preparative GC has a limited range of applications.

The first reason is technical: the processed compounds must be able to be vaporized without decomposition and, even for thermostable compounds, productivity considerations limit the application of preparative GC to compounds with normal boiling points under 250°C.

The second reason is economic: to separate compounds with relative volatilities greater than 1.2, distillation is often less expensive.

Implementation

Figure 1 shows a schematic flow diagram of a typical preparative GC. Typical values of temperatures and pressures are given at different points of the process. The range of operating temperatures and pressures used is given in Table 1.

Note that the pressure at the outlet condensers can be subatmospheric. This feature is used to increase the productivity of some separations when the vapour pressure of the sample at the operating temperature is too low. The use of vacuum raises a number of technical problems and should be avoided whenever possible.

Figure 1 Schematic diagram of a large scale preparative GC. 1, Chromatographic column; 2, detector; 3, valves for trap selection; 4, condensers; 5, gas-liquid separators; 6, fraction collectors; 7, recycled fraction pump; 8, carrier gas cleaner; 9, compressor; 10, carrier gas pre-heater; 11, injector; 12, feed vaporizer; 13, feed reservoir; 14, automation.

Column

As in any chromatographic process, the column is one of the most important components of the system. It is heated to maintain the carrier gas and sample temperature constant. Small columns (up to 80 mm i.d.) are placed in an oven. Larger columns are heated by fluid circulating in a jacket. The column is made of stainless steel packed with a stationary phase. Both ends of the column are closed with metal frits.

Any type of stationary phase used in packed column analytical GC can be used for preparative pur-

pose. The only limitations are the cost and the availability of kilograms or tonnes of packing (e.g. a polymer of 2-6 diphenylparaphenylene oxide currently used in analytical GC is too expensive to be used on a tonne scale).

Most applications use a diatomaceous support coated with various liquid phases.

Packing the large diameter column is technologically difficult. Indeed, to be able to scale up results obtained during small scale experiments one must use 'similar' columns of any scale. 'Similar' columns means columns which have the same efficiency. This was the main difficulty encountered by the pioneers of preparative GC: their large diameter columns were inefficient compared to analytical columns and the separations obtained in the laboratory could not be reproduced for production. This problem has been solved empirically by filling the column with the stationary phase under a controlled vibration system. The packing procedure has not been published and is still the property of the column suppliers. Efficiencies

Table 1 Range of temperatures and pressures used in preparative GC

	Temperature (°C)	Pressure (MPa absolute)
Column inlet	+ 50 to + 300	0.1–0.5
Outlet condensers	– 20 to + 100	0.02–0.15

of 800–1000 plates per metre are now commonly obtained. Column life times are several years longer when treated correctly – no liquid flooding and no excessive temperature.

Detector

The function of the detector for preparative work is not to measure the quantity of compounds in the mixture but to help the operator (or an automated system) to determine when the various compounds are being eluted from the column and when the trap selection valves must be operated.

Any detector used in analytical GC can be used but the detector of choice is the thermal conductivity detector (TCD) because it is nondestructive and it can be used online in the full carrier gas flow. Other detectors can be installed on a small split line.

Trap Selection Valves

These valves are controlled by the automated control system. One, and only one, is opened at a given time.

As the compounds are eluted sequentially from the column at different times, they are directed to different traps so that the temporal separation is transformed into a spatial separation.

Condensers

In the condensers, the mixture of carrier gas and vaporized sample is cooled and the sample is condensed out of the carrier gas.

Phase Separators

Here the carrier gas is physically separated from the liquefied sample. The carrier gas is sent to the recycling line while the sample is directed to the fraction collector. The combination of condensers and phase separators is one of the technological key points of the system. It is theoretically easy to separate a liquid from a gas, but if the condensation is not performed properly the sample will condense in very small droplets (fog) which will be carried away with the gas phase. The solution to this problem depends on the nature of the sample and the size of the equipment.

Trapping yields of > 98% can reasonably be expected in practice.

Carrier Gas Cleaners

Separation of the carrier gas and the sample is not perfect and traces of sample may be recycled with the carrier gas, affecting the next cycle of the purification process. Thus, the carrier gas is cleaned by passing it through a bed of activated charcoal. Two beds are installed in parallel: one is used to clean the carrier gas while the other is being regenerated.

Compressor

The function of the compressor is to circulate the carrier gas through the system and to compensate for the pressure drops.

Carrier Gas Pre-heater

The pre-heater brings the carrier gas temperature to the chosen operating temperature.

Injector

The sample is vaporized and delivered to the injector where it is periodically mixed with the carrier gas.

Carrier Gas

Three carrier gases are used in preparative GC – hydrogen, helium or nitrogen. The influence of the chemical nature of the carrier gas on the selectivity is negligible, so the choice will depend on the physical properties of the gases and on the environment.

Two features influence the separation performance. Viscosity governs the pressure drop in the column and consequently the possible speed of the carrier gas and diffusivity influences the mass transfer of the sample in the column and consequently the efficiency.

Whenever possible, hydrogen is chosen because of its low viscosity, high diffusion coefficient and low cost. If, for safety reasons, it is not possible to use hydrogen then helium is the second choice.

Variants

Various working modes can be implemented in preparative GC. They include temperature gradients, multidimensional GC, moving bed or simulated moving bed GC. Although these techniques can theoretically be useful, they are not used in practice.

Temperature programming can be used for selectivity enhancement and/or elution time reduction when the feedstock components have a large range of retention factors but, due to the high thermal inertia of large systems, the time required to re-equilibrate the temperature between two injections is too long and overall productivity is affected. In such cases, the separation is made in several isothermal steps.

Multidimensional chromatography uses several columns online, packed with different stationary phases. One of the fractions eluted from the first column is directed to a second column, where it is further fractionated, while the second column is bypassed when the other fractions are eluted. The advantages of this configuration often fail to compensate for the increased complexity of the process and such separations are made in several steps.

Table 2 Examples of production scales

Column diameter (mm)	Column length (m)	Typical loading capacity (kg h ⁻¹) (tonnes year ⁻¹)		Carrier gas flow rate (Nm ³ h ⁻¹)
40	1–6	0.1	0.7	0.45
80	1–4	0.4	2.9	1.8
125	1 or 2	1.0	7.2	4.2
200	1 or 2	2.5	18	11.5
400	1 or 2	10.0	72	45
600	1 or 2	22.5	162	100

Moving bed GC (also named continuous counter-current chromatography) and its practical variant, simulated moving bed GC (SMB-GC) offer some of the theoretical advantages of the related technique SMB-high performance liquid chromatography (HPLC). In SMB-GC, the feed flow and fraction flow are continuous, thus the thermal control is easier in both vaporizer and condensers. The stationary phase is used more efficiently, thanks to the countercurrent process. However, in SMB-HPLC the complexity of the system is counterbalanced by savings on the mobile-phase consumption. This is not the case in SMB-GC because the carrier gas is already recycled.

Prep GC: What Scale?

Table 2 gives examples of production scales obtained with different column diameters. Of course, these are typical figures and, depending on the particular application, the actual figures may be five times bigger or smaller.

Preparative large scale GC can be used to purify hundreds of grams a week or hundreds of tonnes a year, as shown here.

6 g per injection on a 40 mm i.d. column
 × 4 injections per hour × 24 hrs per day
 × 4 days per week = 2.3 kg per week

1.5 kg per injection on a 600 mm i.d. column
 × 4 injections per hour × 24 hours per day
 × 300 days per year = 43 tonnes per year

Application examples

Over the last 20 years, preparative GC has been used in hundreds of applications, some of which are listed in Table 3.

cis-trans Pentanediene

In this example the *cis* and *trans* isomers of pentanediene with a purity greater than 99% needed to be recovered from a crude mixture (Figure 2). The preparative chromatogram and operating conditions are shown in Figure 2. One of the features of preparative chromatography compared to analytical chromatography can be seen: for productivity reasons, the column is overloaded and the peaks are not completely resolved. In spite of this, the high level of purity obtained for both isomers (99.8%) is a common feature of preparative GC.

Economy of Prep GC: Example

It is not possible to give an absolute purification cost of large scale preparative GC, since much depends on

Table 3 Examples of applications of preparative GC

Paraffins (C ₅ –C ₃₂), olefins	Methyl ionones
Dienes	Anethole (<i>cis-trans</i>)
Vinyl acetylene	Methyl esters of fatty acids (soya, oleic, linoleic, linolenic, stearic, palmitic)
Alkyl benzenes	Thiophenes (2-bromo, 3-bromo, 2-methyl, 3-methyl)
<i>m/p</i> bromobenzo trifluorides	Thenylamine
Benzyl alcohols, benzyl aldehydes	Chlorophyridines
α and β pinenes	Phosphines
Myrcene	Indoles
Camphene	Ylang-ylang
Limonene	Virginia pine oil
Caryophyllene (azeotrope with anethole)	Clove oil
α and β cedrenes	Fennel oil
Nerol, geraniol, citronellol, eugenol	Lemongrass oil
Farnesols (<i>cis-trans</i> , <i>trans-trans</i>)	Orange oil
Citral a and b	Lemon oil
Citronellal	

Figure 2 Purification of *cis* and *trans* pentadiene. Column: 40 mm i.d.; 4 m long; 20% w/w squalane on Chromosorb P. Carrier gas: helium at 5 cm s^{-1} ; 2.6 L min^{-1} ; 35°C . Injection: 4 mL of mixture injected per cycle; 1 cycle every 20 min. Purity: *cis* isomer = 99.8%; *trans* isomer = 99.8%.

the specific application and on the scale of the process.

The example described here is the purification of two heavy alcohols from a complex mixture.

The two alcohols to be collected are only 35% of the feedstock. **Figure 3** shows the analytical chromatogram of the feed and a preparative chromatogram.

Figure 3 Purification of two heavy alcohols. (A) Analysis of the crude, showing the two alcohols to be recovered. (B) Successive preparative injections on an 80 mm i.d. column; one injection of 18 g every 10 min. Note: the recorder chart speed has been changed after the first four injections.

Table 4 Purification cost breakdown for a production of 36 tonnes per year of injected crude on a 400 mm i.d. column

<i>Operating costs</i>		<i>Annual cost (k\$ per year)</i>
Electricity: $1.44 \cdot 10^{12}$ J	Power	33
2000 h per year	Manpower	80
8000 m ³	Hydrogen make-up	11
5% of equipment cost	Maintenance	58
Replaced every 2 years	Stationary phase	62
(at half the cost of a new column)		
	Total	244 k\$ per year
	Total	6.8 \$ kg ⁻¹ of crude
		21.8 \$ kg ⁻¹ of pure product
<i>Investment costs</i>		<i>(k\$)</i>
	Chromatograph	1200
20% of equipment cost	Surroundings	240
Start-up and others	Miscellaneous	160
	Total	1600 k\$
Amortizement over 5 years	Total	320 k\$ per year
	Total	8.9 \$ kg ⁻¹ of crude
		28.6 \$ kg ⁻¹ of pure product
<i>Purification costs</i>		15.7 \$ kg ⁻¹ of crude
		50.4 \$ kg ⁻¹ of pure product

Optimizing the operating conditions has led to the production of 1 kg h⁻¹ for the first alcohol and 400 g h⁻¹ for the second on a column of 400 mm i.d. The yield of the two alcohols was 89% (mass of pure alcohol collected/mass of alcohol injected) and purity was > 95%.

The economics of the process are shown in Table 4 and Figure 4. The final purification cost is 15 \$ kg⁻¹ of injected feedstock. The normal purification costs

for an industrial process range between 10 and 100 \$ kg⁻¹.

Conclusion

Large scale preparative GC is a real purification tool. It is now reliable and economically viable for industrial production. Columns with internal diameter as large as 600 mm are available. The efficiencies

**Figure 4** Purification cost breakdown for a production of 36 tonnes per year of injected crude on a 400 mm i.d. column. Open segments, investment costs; shaded segments, operating costs.

obtained are between 800 and 1000 plates and the scale of production is between 20 and 200 tonnes per year.

Large scale GC can be used for the industrial production of ultrapure compounds or for the selective removal of impurities. For difficult separations, it is economically competitive with other techniques such as distillation. Whenever it is applicable, it is always competitive with preparative HPLC. Its applications are limited to compounds with normal boiling points under 250°C.

Preparative GC works well with a relatively simple technology; thus, over the last 10 years, technological improvements have been limited to automation in line with modern standards and to maintain simplicity. No major improvement is expected in future, except to adapt the process to specific cases (e.g. ultrapurification of gases for the electronics industry with an impurities level as low as 0.1 p.p.b. and simultaneous separation and reaction in a chromatographic column). The number of installations work-

ing throughout the world is limited to about 100, although the potential of the technique is much greater. The future is likely to see the development of some new very large scale applications.

Multidimensional Concepts

The multidimensional approach to solute separation involves the use of more than one column (almost always two columns) arranged in series, such that chosen components in a chromatogram, or selected sections of a chromatogram, are subjected to separation on each of the columns in the system.

Multidimensional methods may include interfacing of a chromatographic column with a multichannel detection system (mass spectrometry, atomic emission, Fourier transform infrared (FTIR), diode array detection and the like). This review will not extend into this area, focusing rather on multidimension gas chromatography (GC) separations. Within coupled separations, especially online and automated systems, simplification of the total sample analysis by incorporation of extraction steps such as solid-phase extraction, solid-phase microextraction, supercritical fluid extraction and other sampling approaches, combined with chromatographic separation, can be considered multidimensional analysis. These will also not be included here, and details on these methods should be sought elsewhere.

Why are multidimensional methods implemented for chromatographic analysis? The usual answer lies in the need for enhanced separation of closely eluting compounds – compounds with similar retention factor, k . Historically, chromatography has searched for better means to resolve compounds; as methods improve, we can separate compounds of closer chemical nature. Traditionally, chromatographers have improved column selectivity to provide a larger magnitude in differences of distribution constant, K (where $K = k\beta \propto t_R'$; therefore larger retention time differences results from increased K differences), or increased efficiency of the chromatographic process with narrower chromatographic bands giving better resolution. The former is achieved by using a stationary phase or separation mechanism with greater discrimination between the solutes to be separated, and the latter by employing narrower-bore columns, smaller particle packing sizes or other physical means to reduce peak dispersion. Very soon in the historical development of GC, it was recognized that one stationary phase would probably not resolve many compounds (hence the plethora of stationary phases that were produced), but also that a given mixture can contain a range of different classes of compounds that may best be separated on different phases. Thus, improved separation may require two columns for the one analysis. Two separate columns means that

the sample must be analysed twice, but when used in a coupled column arrangement the advantages of both columns can be utilized simultaneously. This is the genesis of multidimensional chromatography.

Effective implementation of multidimensional methods for improved solute separation depends on a number of critical parameters. Firstly, each dimension should separate according to different physical or chemical properties of the analytes and we look to specific selectivity differences towards a problem separation. Secondly, an efficient means of interfacing the (two) separation modes is also required. Switching valves or other methods will be needed to redirect the flow stream from one column to another. This may be combined with a method for peak compression or peak focusing between the two dimensions. Finally, the compatibility of the two separation modes must be taken into account. This will depend upon the carrier fluid (gas, liquid) that is used for each mode, and the mechanism by which solutes are retained on each dimension. For example, multidimensional high performance liquid chromatography (MDHPLC) combining strictly normal and reversed-phase modes will present a challenge because of the incompatibility of the mobile phases required by the two modes.

Basic Instrumental Requirements and Considerations

The main concern in implementing a multidimensional separation solution will be how to design the instrumental set-up. The greater the difference between the two dimensions, the greater the potential difficulty in their coupling, since there will be greater dissimilarity in the mechanisms of separation. The wide choice of column chromatography separation methods explains why the coupling or interfacing

may present a challenge. If the two dimensions are of the same chromatographic type – GC–GC, HPLC–HPLC, supercritical fluid chromatography (SFC)–SFC etc. – the task is not so problematic. Where different carrier phases are required for the two dimensions, chromatographic integrity must be maintained. Transferring a solution phase from HPLC to capillary GC or SFC requires an interface that can effectively introduce analyte into the narrow-bore column without compromising band dispersion, and whether analytical scale or large volume solvent injection is to be used determines the interface complexity.

Table 1 presents a summary of the potential successful multidimensional column chromatography methods. Some options will be generally incompatible, such as IC coupled with GC, since exclusion of the electrolyte carrier fluid from the GC system will be difficult, and ionic analytes for which IC is usually used will not be suited to GC analysis. The suitability of HPLC–GC and GPC–GC for volatile organics is the reason why these liquid-phase first-dimension separations are useful for sample differentiation prior to the GC step. **Table 2** further outlines various procedural aspects of selected multidimensional methods.

For multidimensional GC (MDGC) analysis, it is not a difficult task when dealing with relatively low boiling mixtures to couple two columns together, and to have gas-sampling valves or a flow-switching device to allow transfer of effluent. The classical Deans switch relies on pressure differences to pass carrier flow in different directions. **Figure 1** presents a schematic diagram of a typical commercial MDGC system, comprising one oven, two columns, two detectors, a midpoint restrictor at which point the diversion of column flow to either the first detector or the second column occurs. A cold trap focuses heart-cut

HPLC-GPC	Capillary GC	Large volume injection	Prior class separation before GC step

fractions, and a solenoid-controlled shut-off valve closes the flow through to the monitor detector and effects the transfer of the flow of column 1 to column 2.

Direct coupling of two or more columns, with all the effluent from one column passing wholly into the second column without hindrance (see later for variations on this theme), is normally not considered a MDGC analysis because MDGC methods should lead to greater *peak capacity* for the total system. Capacity may be thought of as the total available or achievable peak separation on a column. In simple terms, this is the total retention space divided by an average peak width parameter defining acceptable neighbouring peak resolution, i.e. the maximum number of peaks, resolved to a given extent, which can be produced by the system. Consider temperature-programming analysis. Assuming that the total chromatographic adjusted retention time is 90 min, and each peak basewidth is 10 s (peak widths may be approximately constant across the whole analysis, depending on the temperature ramp rate chosen), then a maximum of 540 baseline separated peaks could be recorded on this column. In practice, the actual number would be much smaller since the peaks are not eluted uniformly over the total time of the analysis.

Expanding System Capacity

Statistical methods have been employed to determine the ability of a column to resolve a complex mixture of compounds, assuming their distribution within the column to be entirely random. This theoretical analysis is informative, but typical complex mixtures must be treated on a case-by-case basis. The chromatographer must define the information required from an analysis; there may be no need to resolve every peak in a mixture if the required target solutes are only a small fraction of the total components. An optimized separation need focus only on those components which must be analysed. For example, the analysis of benzene and toluene in gasoline fractions, where only the resolution and quantification of these compounds

are required, means that the measurement of all other components is of less or even of no concern.

The capacity of the total system (or the restricted region about the target solutes) will be expanded in the multidimensional analysis. Specific regions of the effluent from the first column must be isolated and these small fractions transferred to the second column. These two columns may be referred to as the pre-column or first dimension, and the analytical column or second dimension.

Consider the above GC column with a capacity of 540 peaks. If this is coupled to a second column with capacity of, for example, 280 peaks, and if the two columns represent completely orthogonal separations, we would have a theoretical capacity of $540 \times 280 = 151\,200$ peaks. More generally:

$$n_{\text{tot}} = (\bar{n})^z$$

where n_{tot} is total peak capacity, \bar{n} is the average capacity on each column and z is the number of coupled columns.

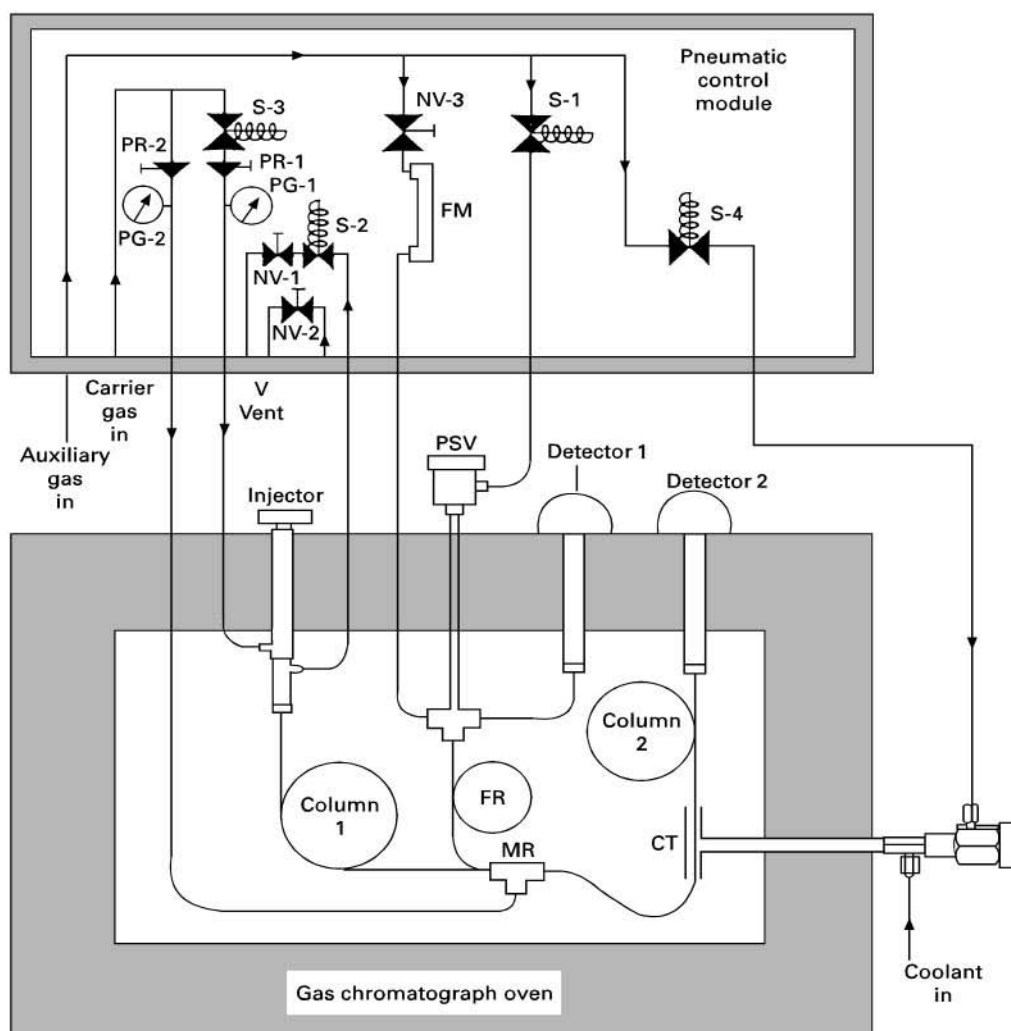

This can only be possible if the full capacity of each dimension can be achieved in the MDGC analysis. This is not normally so; it depends critically on the manner in which the column interfacing is performed, and how the transfer and subsequent second-dimension analysis is carried out. In fact, with selected heart-cut analysis, the total system capacity is better described as the summation, rather than the product, of the capacity of the two coupled columns:

$$n_{\text{tot}} = 2\bar{n}$$

or, more generally:

$$n_{\text{tot}} = \sum n_1 + n_2 + \dots n_z$$

Consider a first column with a small unresolved group of, say, five peaks each of 10 s basewidth, eluting over a period of 35 s which is transferred to the second column. The peak capacity of the first column in the region of interest is only 3.5. If the second column has the ability to separate these peaks

just to basewidth, then its capacity towards the target solutes is 5. (If the peak separation is random, we will require a higher peak capacity in order to be assured that the five peaks will be separated.) In GC, solute boiling point plays a key part in the retention of compounds, and superposed on this primary retention parameter will be secondary properties such as polarity of the column and solutes, defining solute-

specific interactions. Since each column's retention depends in the first instance on the overall volatility of each component, then the heart-cut or transferred solutes cannot be distributed over the total elution space of the second column. Rather, it is restricted to the range that the combined effect of boiling point and polarity imposes on the compounds. A non-polar first column means close eluting solutes have similar

boiling points. A polar second column will enhance solute polarity differences to achieve separation. **Figure 2** shows examples of heart-cutting poorly resolved sections of one column to another column. If the solutes subsequently elute relatively close together, much of the theoretical capacity of the second column is not employed.

In many MDGC systems, a cryofocusing step is used at the start of the second column to collect heart-cut fractions as a narrow band, as shown in **Figure 2B** centre. When the cryogenic fluid is turned off, the solutes recommence their travel on the second column, starting at the same initial position and time. If unresolved compounds from the first column are

separated, the aim of the experiment is achieved. The use of a second oven, in which the second column is located, may require a cold trap since just keeping the second oven at a low temperature may not be sufficient to immobilize the solutes. If trapping is not required, the second oven may track the temperature of the first oven.

The need for a cryogenic trapping procedure requires further consideration. Since it will focus solutes at the start of the second column, it will also remix partially resolved compounds. Depending on whether the solutes reverse their relative retention on the two phases, the action of focusing the solutes may either improve or worsen the separation.

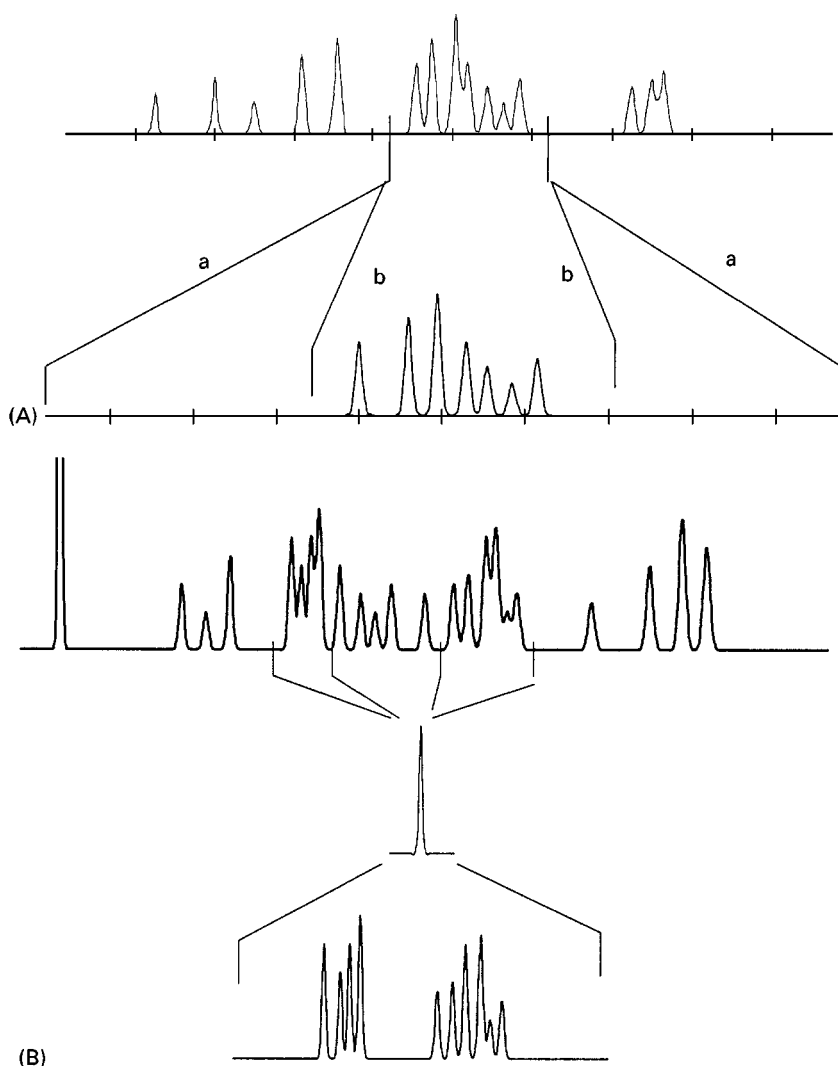

Figure 2 (A) Heart-cutting the poorly resolved section of the top column to the bottom column improves separation, but the full capacity of the second dimension may not be fully used. A second-dimension analysis, which only requires the space shown by lines labelled b, would be preferable to that shown by lines labelled a, where excess analysis time would result. (B) Two heart-cuts are performed on the first dimension (top). Both heart-cuts enter one cryogenic trap with all components recombined into one band (centre). The second-dimension analysis (bottom) is then used to provide greater selectivity difference for the range of solutes and enhanced separation of the components.

In summary, MDGC may be used in the following arrangements:

- single oven, with or without a cryotrap
- dual oven, with or without a cryotrap
- single or dual oven with multiple sorption/collection traps
- single oven with rapid second-dimension analysis and modulated transfer system – the so-called comprehensive 2D GC.

Figure 3 summarizes a number of different arrangements for performing multidimensional chromatography. Irrespective of the dimension types, the coupling must enable the flow stream to introduce solute into the second dimension. Direct coupling (or pressure tuning in GC) need only use a column connector, but other methods use multiple heart-cuts into one storage reservoir, as indicated by the circle shown in 3A (e.g. a single cryotrap in GC), or separate storage devices with discrete analysis of each, as shown in 3B, or a specially designed modulator to allow continual sampling/analysis of fractions from dimension 1, as in 3C (see later). In the case of method 3A, 2D will probably require a broad range of analysis conditions since collected fractions will have a wide volatility range. In 3B, each separate 2D analysis need only be performed over a limited range of conditions, selected according to volatility considerations.

Figure 3 Coupling two dimensions, transferring selected bands and completing the second-dimension analysis can involve a range of procedures. (A) The second separation dimension can be a single chromatographic analysis, with selected dimension 1 (D₁) heart-cuts combined, e.g. in a cold trap, prior to dimension 2 (D₂). (B) A series of second-dimension analyses, each for an individual D₁ heart-cut, can be run with each heart-cut stored in a separate sample reservoir, e.g. sampling loops in HPLC or cold traps in GC. (C) By operating the second dimension in a rapid repetitive fashion, the comprehensive chromatography method is possible.

In regular MDGC, there will be a limited number of second-dimension analyses, or a limited number of heart-cut events. Conventionally, both dimensions will employ columns of reasonably normal types in respect of lengths, diameters and carrier gas flow rates.

In an offline system, or where fractions are collected in a storage section prior to introduction into the second dimension, such as a sampling loop in HPLC, the time between collection of heart-cut and second-dimension analysis might not strictly represent a continuous coupled analysis.

MDGC for Trace Enrichment

A capillary column has a limited sample capacity. Excessive amounts of sample lead to nonlinear conditions and broadened peaks are obtained. Such broadening can obscure small peaks of interest which elute with a similar retention factor to that of the large component, affecting quantification and identification of the trace solute. In MDGC, sample may be injected into a packed column which has a greater ability to maintain linear conditions at higher injected amounts. The zone of enriched trace component can then be heart-cut to a capillary column. Most of the major component will have to be excluded by the heart-cut event, and since now it does not overload the capillary column, there will be less probability that it overlaps the trace solute. Much more of the trace solute is passed to the capillary column than is otherwise possible. This application does not necessarily require different column phases on both the packed and capillary columns. The first column can be considered to be part of the sample introduction step into the second column.

Use of a Series of Parallel Heart-cut Reservoirs/Traps

Parallel traps are used to store successive heart-cut fractions prior to subsequent analysis. These might be liquid-phase loops (HPLC) or cryogenic traps (GC; Figure 3B). An array of packed cryogenically cooled traps may be used to collect selected fractions of heart-cut effluent from a capillary GC pre-column. The individual traps are then eluted into a second analytical capillary column, chosen for particular suitability to the required analysis. The effluent from the analytical column may then be split to different detectors, and the use of mass spectrometry/flame ionization detector and FTIR has been described, with FTIR receiving the larger flow due to its less favourable detection sensitivity. This procedure has been demonstrated with petroleum samples, where

FTIR is most advantageously used for isomers of compounds such as the xylenes. However, the complications arising from multiple trap management will reduce its attraction for many analysts.

Backflushing

In GC analyses where a sample consists of a wide boiling range of components, and where their prior separation is either difficult or troublesome, injection will introduce the low volatility components into the chromatographic column. If the target solutes are those that are eluted quickly, considerable time must be spent waiting for the high boiling point components to be eluted before the next analysis can be commenced. In MDGC, it is possible to reverse the flow in the pre-column (refer to column 1 in Figure 1) to back-flush the heavy constituents out of the column and vent them through the split vent line. This can be completed whilst the higher volatility components are being separated on the second column. This flow switching will be commenced when the desired solutes have passed the midpoint valve between the two columns (back-flushing is the oldest form of MDGC and has been employed since the earliest days of GC). Back-flushing can likewise be easily incorporated into other coupled separation systems such as MDHPLC.

Pressure Tuning

The technique of pressure tuning involves variation in the midpoint pressure between coupled columns to alter overall solute selectivity. This is not strictly an MDGC method, and has been given the term multi-chromatography in order to differentiate it from regular MDGC. However, pressure tuning is possible on regular MDGC systems, and some specific multi-dimensional results can be achieved on multi-chromatography pressure-tuned systems. The unified chromatography procedure, promoted by Bartle, alters the characteristics of the carrier phase during an analysis, for example progressing from GC to SFC conditions by applying a pressure programme to the carrier stream. Thus, one column is used, but different chromatography mechanisms are employed. This variation is again not strictly multidimensional. The pressure-tuning arrangement is shown in Figure 4.

Compounds are immediately presented to the second column as soon as they are eluted from the first column; their motion is not hindered by trapping or any other similar solute-focusing effect. Changing the midpoint pressure alters the relative flows in each column. Flow change by itself does not alter the capacity factor on either column (i.e. k is constant),

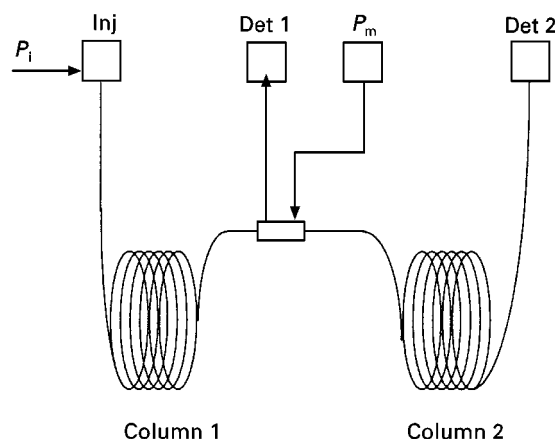

Figure 4 The pressure-tuning method involves a coupling between the two columns where additional pressure (P_m , midpoint pressure) can be applied above the natural pressure. P_i , inlet pressure; inj, injector; Det 1, Det 2, detectors 1 and 2.

although of course temperature change may affect relative k values. However, the overall k value may change dramatically with midpoint pressure changes. The contribution of each column in determining overall solute capacity on the system is varied, and so relative solute positions may change and best separation conditions may be determined. This procedure is essentially a continuously variable (at least over a given range) phase composition method, simulating column phases of selectable polarity based on the two phases comprising the coupled columns. It is possible to predict the effect of pressure on the overall separation, since individual retention factors on each column can be determined. The effect of carrier flow rate on each individual column's performance should still be considered. Figure 5 represents results which may be obtained, with the unretained peak time giving retention factors on each column. Peak overlap and exchange of relative retention of components are precisely what may be seen experimentally.

For a given column length, the total separation space does not increase in this method.

Comprehensive Multidimensional Chromatography

Comprehensive multidimensional chromatography is closest to a true continuous multidimensional column method since it subjects every emerging peak in the first dimension to second-dimension separation in almost continual fashion. Figure 3C is a representation of this approach. The term comprehensive chromatography is attributed to Bushey and Jorgenson, who demonstrated the advantages of the technique for coupled HPLC dimensions. Two major

Figure 5 Pressure tuning allows retention factors to be determined on each separate column section provided t_R s of compounds (solid lines) and t_M (dotted line) are known on each dimension. After the midpoint, various solutes may swap position, possibly leading to better overall separation. The effect of the pressure tuning can be predicted by moving the right-hand vertical line along the horizontal axis.

variations depend on whether all the column flow or only a portion from the first column is transferred to the second column. These require different technical implementation of column coupling.

The second column elution time must be very short with respect to that on the first dimension – less than the frequency at which the first column effluent is sampled. This ensures that each second-dimension elution is completed before the subsequent band is introduced into the second column. Result presentation is best if the second-dimension analysis is rapid with respect to bandwidths on the first column, for example, a second-dimension analysis time about one-fifth of the peak width time on the first column. Given this requirement, first column performance leading to broad peaks may be required. The two columns chosen should ensure orthogonality. Retention of compounds in dimensions one and two can be defined as 1t_R and 2t_R respectively.

The final chromatogram will be a two-dimensional array of retentions, with a third dimension of peak height, leading to a contour plot chromatogram. Data presentation protocols and concepts such as retention indices, quantitative analysis considerations and relationships between peak position and phase polarities are only just being explored. Much further work is needed to evaluate these systems fully. **Figure 6** demonstrates how the three-dimensional data are presented in terms of a contour plot. The peak contour comprises a series of slices in the second dimension which is reconstructed as a peak with dispersion in both dimensions. The original first-dimension separation is shown.

In the comprehensive gas chromatography (C(GC)²) method, peak compression by a means of a focusing step between the two dimensions may be advantageous. This allows a very narrow band to be introduced to column 2 and allows the best peak capacity to be achieved on this column. Ideally, overlapping components in dimension 1 will be resolved on dimension 2. Peak compression of 20–50 times have been demonstrated, and this immediately translates into significant peak sensitivity enhancement with C(GC)².

In HPLC, the collected fraction of effluent would typically be analysed on a conventional column, so it would have a typical retention time in minutes.

Comprehensive Gas Chromatography

The (GC)² part of the abbreviation serves to indicate the multiplicative capacity of the system, and the term comprehensive reflects that the full suite of peaks from the first dimension is analysed.

The second dimension analysis time will be about 5 s or less, and the second dimension, comprising a short, high-phase ratio, narrow-bore open tubular column, might have a total peak capacity of only 10–20 peaks. C(GC)² uses first and second dimensions

Figure 6 Peak contour representation of two-dimensional separation in comprehensive chromatography.

at the same oven temperature, allowing the second column effectively to resolve on the basis of polarity difference between the two columns. If adjusted properly, the full peak capacity on the second dimension should now be available for separation, and the total peak capacity should be the product of the first column capacity and the capacity available on the second column at any chosen operating temperature (the second column operates almost isothermally for each individual analysis).

Having a high peak capacity should not be too critical on the second column, but phase polarity or selectivity difference should be carefully chosen.

Peak compression, followed by fast second dimension analysis, results in improved sensitivity of detection; if a 5 s band of effluent from column 1 is compressed and leads to a detected peak width of 250 ms, a 20-fold sensitivity increase should result.

Technically, $C(GC)^2$ with compression in time requires novel procedures. Two systems have been described for $C(GC)^2$ employing band compression. One is based on a rotating elevated temperature modulator which passes closely over the junction between the two columns, incorporating a thick film accumulator section between the columns at the junction. An alternative device employs a longitudinal oscillating cryogenically cooled trap that can collect and focus solute from the first column, then pulse or remobilize the narrow band into the second column.

Given the need for very rapid analysis, rapidly recording detector systems are required.

Peak position in the two-dimension separation space will now be a complex function of volatility and polarity, determined by the individual mechanisms of the two columns chosen, and a full interpretation of the $C(GC)^2$ method is required in this respect. Possibilities for class separation demonstrate that the method has potential for multiresidue and screening applications, and characterization of petroleum products.

Pyrolysis Gas Chromatography

C. E. R. Jones, Redhill, Surrey, UK
Copyright © 2000 Academic Press

Introduction

The gas chromatographic process is wholly dependent upon solutes having significant vapour pressures

at the upper limiting operating temperature of the chosen solvent so that the partition of those solutes between the mobile and stationary phases affords viable separation.

Such a limitation prohibits the analysis of any intractable samples (i.e. potential solutes) unless the means to modify them are invoked.

In order to attain that goal, thermal fragmentation of such samples was proposed with the object of providing volatile products that would yield to conventional gas chromatographic separation. Having identified the resultant products and made the basic assumption that the fragmentation of the sample was complete, one then had to reassemble the jigsaw in order to elucidate the nature, even the identity, of the original sample. In any event, meaningful deduction must be implicit with the base assumption that one is considering primary degradation products, hence, pre-knowledge of the character and/or chemistry of a particular sample is often needed in order to arrive at a definitive conclusion.

Naturally, thermal degradation is a method that requires educated application in that resultant fragments must be of a molecular size that allows sensible interpretation. Obviously, a large number of small fragments are of little value since ultimately most organics will break down to very light hydrocarbons, both saturated and unsaturated, carbon oxides, water and a variety of inorganics of greater volatility, e.g. ammonia, hydrogen chloride, oxides of nitrogen or sulfur.

Although Davison, Slaney and Wragg are credited with the introduction of pyrolysis gas chromatography (PGC) in 1954, there is ample evidence that several workers were developing the method even earlier. It was immediately recognized that the technique was invaluable for the identification of synthetic polymers whose commercial viability depended on suppression of their chemical identities. Thus there was a good reason to conceal the fact that one could not only access competitors' products but learn as much or even more about a particular product than the manufacturer!

Whatever has been said and written about slow pyrolysis is very much open to question. Certain workers have long advocated the use of slow temperature ramps to reveal progressive transitions in the sample. It does not seem unreasonable to suggest that the approach is untenable as homogeneity of the sample is imperilled. Heat transfer within that sample and variable rates of diffusion of any products through unaffected, untransformed, undegraded, affected, transformed or degraded sample cannot be controlled and therefore leaves the question 'what is one actually looking at?' unanswered.

Terminology

It is now agreed that pyrolysis (alternatively, thermal breakdown, thermal cracking, thermal decomposition, thermal degradation or thermal fragmentation) is the transformation of a compound into another substance or substances through the agency of heat

alone. Indeed, most pyrolyses are thermal decompositions or fragmentations. Be warned that the formation of larger rather than smaller molecular weight substances is not only possible but, under certain conditions, highly probable (as the writer learnt to his cost very early in the development of the method).

A pyrogram is a chromatogram of a pyrolysate. It was originally used in the sense of a fingerprint and a tentative identity assigned after comparison with a library of known pyrograms which had been prepared under as near identical conditions as was then possible. With the advent of coupled gas chromatograph/mass spectrometer and discriminative mathematical treatments of vast quantities of data, the technique was promoted to a much higher plane but it should be remembered that statistical methods are, on occasion, far from infallible.

Modes of Pyrolysis

Many practitioners still prefer to fabricate their own pyrolysers without a true appreciation of the many factors that influence the results. Both inter- and intralaboratory reproducibilities are affected by introducing self-inflicted intangibles, inevitably reflected in differences of design and operating conditions.

The scale of these problems was highlighted by the outcome of the European PGC Correlation Trials arranged by the Gas Chromatography Discussion Group (now the Chromatographic Society) as long ago as 1968–1975; this was later duplicated on the same samples by Walker *et al.* in the USA. Gratifyingly, the two sets of results were encouragingly similar but, sadly, not identical.

However, despite serious efforts to introduce effective levels of standardization in both apparatus and practice, the technique fell into disrepute. This was principally due to a plethora of home-made pyrolysers, the conditions of their use and, finally, the total inability of inexperienced would-be practitioners to recognize the many pitfalls. Even worse, the method became stigmatized as 'dirty analysis' because of the damning evidence of tarry and/or carbonaceous residues remaining in the pyrolysis zone. The philosophy was that incomplete analysis has little credibility unless an experiment is focused on the observation of a unique independent event which is an indisputable marker of a specific situation.

The Furnace Pyrolyser

The furnace pyrolyser consists of a relatively small, electrically heated, isothermal chamber, preferably integral with the injection port of the chromatograph. Any connecting line should be similarly heated for as short a time as possible to minimize diffusion and

secondary reactions. The furnace itself must have a large thermal capacity to avoid any significant temperature sag upon introduction of the sample and its carrier. It must be so constructed as to allow the sample, contained in a miniature 'boat' or crucible to be introduced through a purged airlock by means of a suitable mechanism.

The most serious drawback is, of course, the presence of a significantly large dead volume where turbulence could cause the pyrolysis fragments to remain in the pyrolysis zone for a sufficient length of time to produce secondary fragments and thus confuse the picture.

The Filament or Platten Pyrolyser

The filament or platten pyrolyser is an electrically heated conductor having a relatively large usable surface area contained in a minimal volume. **Figure 1** shows a recent example of the device which has been fabricated from a piece of Pyrotenax topped by a suitable finned cooling cap carrying a socket accepting a two-pin plug. The filament itself is initially a 2.5 ohmic length of 22 wire gauge platinum, chromel-alumel, nichrome or other resistance wire tightly machine-coiled to an internal diameter of 1.0 mm, tensioned across the central conductor and an extension of the sheath to a 2 ohmic length and spot-welded in place.

Obviously the length of the Pyrotenax barrel must be tailored for a particular injection port and the port itself reamed out so that the annular space between the inner wall of the injection port and the Pyrotenax outer sheath is no wider than 0.2 mm. This is to combat the probability of a back-pressure pulse, for when the pyrolyser is fired at a temperature of, say,

700°C there is a large local carrier gas expansion. Due to the dynamic resistance of the chromatographic column this must be accommodated in the direction of the gas flow to prevent both diffusion and the risk of reverse flow that passes the pyrolysate through the pyrolysis zone a second time with the risk of further thermal modification. This is absolutely essential to observe the terms of good practice. It must also be taken into account that there is a temperature coefficient of resistance which must be accommodated and suitable measures taken to ensure reproducibility.

Temperature control is best achieved by making the filament or platten one arm of a Wheatstone Bridge circuit and adjusting the balance to control final temperature. The system is calibrated by inserting the pyrolyser in a dummy column maintained under the chosen chromatographic operating conditions and observing the melting points of a series of inorganic salts. It should be noted that the current density applied to the filament must be conducive to rapid heat-up for it is essential to attain the pyrolysis temperature in a few milliseconds (if not microseconds) and ensure a hold for, say, no more than 1–2 s by means of associated timer circuitry. In that time the pyrolysis products are on-column and being separated – ideally the thermal profile should be a square wave.

These instrument combinations and their operations, described above, have been tried and tested by the writer in many laboratories throughout the world over many years and have proved easy to handle by laboratory technicians. Pyrolyses themselves are eminently reproducible provided that the sampling

Figure 1 A modern filament pyrolyser together with its modified chromatographic injection port. Inset: detail of mounted filament.

procedure is standardized (see below) and equipment is maintained in as near-sterile conditions as reasonably possible.

At best, the pyrolyser should be cleaned by heating at a higher temperature in an inert atmosphere between every shot. This serves two purposes: first, it removes traces of any residues and second, if cleaned on-column, the completeness of the pyrolysis is verified. In the event that this process is too time-consuming it is better conducted externally or under back-flush conditions.

The possibility of the heating substrate acting as a catalyst has never been completely negated despite a series of standardized experiments conducted by Jones on a variety of metals, both before and after gold-plating. A second hazard is found in the build-up of carbon on the filament itself; this modifies the pyrolysis surface.

The Curie Point Pyrolyser

The adoption of inductive heating by Giacobbo and Simon in 1964 was very quickly recognized to possess many virtues. The most important is found in the fact that final skin temperature (the Curie Point) is a function of the composition of the ferromagnetic conductor when subjected to a given radiofrequency electromagnetic field. Additionally, the skin heating rate is constant for wires of identical cross-section. Moreover, there is no risk of cross-contamination as a 'virgin' wire can be used for each pyrolysis. Sterile storage and handling of new wires is the only precaution necessary.

Table 1 lists the constitutions and Curie Point temperatures of a range of ferromagnetic conductors.

It should be remembered that an energized radiofrequency coil generates an ellipsoid field. In consequence, the Curie wire should be located in such a position that the sample it carries is as near to the centre of the coil as is practically possible. In order to avoid any artefact introduced by an end effect, Jones pointed out that the use of a Helmholtz coil gave a stretched field uniform over a greater length of the coil and hence precise location of the sample became less critical.

A cross-sectional diagram of the built-in injection port receptor designed by Jones is pictured in Figure 2.

Figure 3 shows the Curie Point pyrolyser insert in cross-section. Obviously, a simpler, but dimensionally similar insert can be used for conventional liquid sampling so that the integrity of any comparative exercise is preserved.

Figure 4 details the cryogenic focusing unit contained in the oven necessary to counter the inevitable degradation of column performance by the unavoidable presence of an unusually large dead volume

Table 1 Metals and the composition of their alloys which give a usable range of Curie Point temperatures

<i>Metal or alloy (composition %w/w)</i>	<i>Curie temperature (°C)</i>
Fe/Ni (78.5% Ni)	200
Fe/Cu/Ni (9.0% Cu/36.0% Ni)	300
Ni	358 ^a
Fe/Al (16.0% Al)	400
Fe/Mo/Ni (4.0% Mo/79.0% Ni)	460
Fe/Ni (50.0% Ni)	500 ^a
Fe/Ni (68.0% Ni)	600 ^a
Fe/Co/Ni (7.0% Co/70.0% Ni)	650
Fe/Si (4.0% Si)	690
Fe/Co/Ni (25.0% Co/45.0% Ni)	715 ^a
Fe/Si (3.0% Si)	740
Fe	770 ^a
Fe/Co (50.0% Co)	980 ^a
Co	1130 ^a

^aThe metals or alloys most commonly available drawn as suitable wires. Warning: temperatures quoted are approximate because of impurities and the method of manufacture. which must encourage diffusion as well as other attendant difficulties. A timer/control unit triggers a solenoid valve to close a liquid nitrogen reservoir to build up pressure. A second solenoid valve opens a feed line to allow a jet of liquid nitrogen to play on the front end of the column for 2 s at the moment of pyrolysis. Warm-up of the chilled zone to column temperature to liberate the pyrolysate is near instantaneous by reason of the large thermal capacity of the oven/column assembly. Finally arrangement is made for pressure release in the liquid nitrogen vessel; the cycle is replicated for conventional liquid sampling.

Laser Pyrolysis

Both ohmic and inductive pyrolyses are initiated by heating the back of the sample (which can be a serious disadvantage: see Sampling, below). In contrast, laser heating involves surface initiation of the degradation process. Table 2 compares the pertinent elements of the two processes.

One of the recommended sources of energy is a pulsed neodymium-YAG laser which is mounted in parallel with a neon laser aligned on an identical light path to afford a sight line to aid selection of the required target.

Very rapid heating requires a high thermal flux; perhaps the idea of a pulsed laser is far too simplistic when only the thermal aspects of laser-induced pyrolysis are considered, for the process involves a short, intensive photolysis which radically differs from our present understanding of the pyrolytic process.

A phase-coherent laser beam delivers packets of photons in a nanosecond pulse into the surface of the sample. It should be noted that if the sample is optically transparent, a pigment must be added to provide absorbing centres to promote the ionization of the molecules in the sample surface.

Table 2 Comparison of two heating processes

	<i>Ohmic inductive heating</i>	<i>Pulsed laser heating</i>
Substrate	Metal platten or coil, or ferromagnetic probe	Sample continuum (pigmented if necessary)
Sample	Solution or sonic dispersion	Solid chip or compacted powder
Heating geometry	Sample back	Sample front
Heating rate	10^3 K s^{-1}	10^7 K s^{-1}
Cooling rate	-10^3 K s^{-1}	-10^6 K s^{-1}
Pyrolysis condition	Both in an inert atmosphere	
Time	100–2000 ms	4–800 μs
Limitations	Possible catalytic effect(s). 'Blow-off' due to gaseous products at substrate causing molten undegraded sample to balloon and burst	Heat input/take-up indeterminant. Possibility of plasma reactions and photolysis. Transparent samples need pigmenting

Figure 4 Diagrammatic cross-sectional representation of the pre-column concentration unit (not to scale).

The ionization process can be explained either by electron tunnelling or by multi-photon absorption. After initial ionization, photon energy is selectively absorbed by electrons above the sample surface and the hot electron cloud or laser plume collapses into the sample surface whereupon molecular fragments are pumped into the hot plasma. On termination of the pulse the system rapidly returns to ambient.

The plasma, consisting of unbound electrons, free atoms and those few radicals of unusual stability, is in kinetic equilibrium but when the unbound electrons return to their accustomed atomic states the resultant species quench directly from the plasma and provide an informative series of products. However, other species can arise from thermal scissoring within the solid sample and a further series of products can then result from interaction of those species with certain plasma components.

Figure 5 Cross-section of laser pyrolysis cell insert (not to scale).

A laser pyrolysis cell insert for the chromatographic injection port receptor (Figure 2) is shown in Figure 5.

UV Degradation

The only other energy source that has been used in the context of pyrolysis is the UV generator introduced by Juvet, who promulgated its use for stability studies.

The very slow reaction rates associated with time-dependent processes such as the weathering of synthetic coatings, adhesives, rubbers and textiles are in no way compatible with the fundamental concepts of pyrolysis as heretofore enunciated. Therefore the use of UV excitation has shown no advantage over traditional techniques and, in consequence, was abandoned.

Sampling

One of the foremost and, perhaps least appreciated of the initial problems is that of sampling. Sample size and distribution are critical because organics, which comprise the vast majority of potential samples, are invariably very poor conductors of heat.

Jones and Moyles enunciated the thin film concept in 1958. This is based on comparisons of strictly controlled pyrolytic events on the milligram, microgram and sub-microgram scales. Pyrograms of simple substances were demonstrated to be of ever-increasing complexity as sample size increased. The phenomenon was eventually shown to be due to diffusion of degradation products through partially degraded sample and longer residence times in the vicinity of the pyrolysis zone, which led to unwanted secondary reactions. For these reasons it is advisable to work on the nano- or even picogram scale whenever possible.

It should be realized that the most informative evidence leading to an unambiguous conclusion lies

in the certainty that all the scissive events viewed are primary reactions (notwithstanding the fact that most primary reactions must be the formation of free radicals which are themselves stabilized by recombination). Therefore it is imperative to regularize the situation as best as possible. That is, the fastest thermal gradient with respect to time within the body of the sample, a condition that is only satisfied by presenting the sample as a very thin film, ultimately as a uni-molecular layer. Unfortunately, the very nature of most samples submitted for pyrolysis prior to gas chromatography is that they are reluctant to form the uni-molecular layers that are theoretically essential. So a compromise has to be made and as thin a layer is distributed on the effective surface of the chosen pyrolyser as is practically possible.

When a sample is soluble in a volatile solvent the deposition problem is ameliorated but immediately poses further problems. What if the solvent lacks wetting power for metallic surfaces? Addition of an amount (e.g. up to 5% v/v) of tetrahydrofuran or dioxan as a wetting agent rarely affects solubilization and overcomes the beading that characterizes a non-wetting system.

After deposition of the sample, residual solvent is best removed in a vacuum oven at a temperature little above ambient. However should the sample be insoluble it is reduced to fine powder by slow freeze-grinding in order to minimize the risk of thermal degradation arising from localized heating due to mechanical friction. It is sonically mixed with a blend of a polar solvent and water containing 1% w/w of a refined natural gum or a purified poly(vinyl alcohol), and then stuck on the probe and dried in the manner already suggested. Conflicting pyrolytic fragments arising from breakdown of the adhesive used can be subtracted from the total pyrogram if deemed necessary; experience, however, has shown that there is little significance in any contribution from the presence of a relatively small amount of an alien material provided that the same routine is used in comparative exercises.

It cannot be emphasized enough that much depends on maintenance of strictly sterile conditions as always.

Applications

The universality of the application of PGC methods has long been a matter of dispute. Without doubt, most disagreement has come from those who have failed both to appreciate and then to observe the basic precepts outlined in this article.

Historically, the method found the greatest initial value in the identification of synthetic macromolecules, while subsequent work by Shin Tsuge in Nagoya led to the elucidation of polymeric microstructures.

There followed studies explaining mechanical strength, cold-drawing properties, film-forming capabilities, cohesion within films and their adhesion to a wide variety of substrates, pigment binding, and the mechanisms of cross-linking processes.

Reiner was the first to appreciate that the difference between a synthetic macromolecule and a biopolymer was merely that of environment. In consequence his work on microbacter and cellular transformations must now be considered to be the foundation for much of today's clinical and pathological practice.

The FOM Foundation group in Amsterdam, under the stewardship of Meuzelaar, expanded the field of application of PGC in parallel with their pioneering work in pyrolysis/mass spectrometry. There, their initial focus was on a broad spectrum of natural polymers.

Wheals, of the British Metropolitan Police Forensic Laboratory, introduced PGC in criminology and developed techniques that formed a basis for standard practice in forensic laboratories. Results are now generally accepted as evidence in many criminal jurisdictions.

The virtue of the very small samples needed for the vast majority of diagnoses has seen adoption of PGC, conducted under very carefully controlled conditions, for the preservation of many art gallery and museum exhibits. For example, deteriorating ancient varnishes and pigments have yielded their secrets and pictures may be cleaned and/or restored without further damage, which will benefit the generations still to come.

Environmental and ecological applications are now coming to the fore. The analysis of occlusions of harmful volatile organics on air-borne particulates has contributed much to our understanding of their significance in the context of respiratory problems.

Bracewell was among the first to develop PGC for the assessment of soil fertility. More recently, De Leeuw graphically demonstrated that reasonably volatile organics such as polycyclic and halogenated hydrocarbons could be excised from very complex matrices (e.g. soils or sediments) by flash evaporation by imposing a millisecond thermal ramp on the sample.

Jones and Vanderborgh employed PGC in conjunction with other pyrolytic studies in their elucidation

of coals. They demonstrated that their apparent heterogeneities were due to guest markers of the environments of both the initial debris and the maturation cycle then occluded in a formal cross-linked, spiral double-ladder polymer. An outcome of their work was a proposal for a 'down-hole' mole chromatograph containing a miniature laser pyrolysis cell designed to be lowered into a petroleum exploration, pilot drill hole for real-time *in situ* stratigraphic monitoring of hydrocarbons. Such an approach must certainly be quicker and cheaper than core extraction and subsequent off-site analysis.

In the light of the diversity of applications given here, it is more than apparent that PGC's potential is only limited by the wit and imagination of the educated user.

Conclusions

Despite the early stigma of unreliable and dirty analysis, PGC survived because of the dedication of a small handful of workers who were convinced that most practitioners were to blame for their failures rather than the tool they purported to use.

The method has re-emerged as an active member of the analytical chemist's armoury. This is handsomely substantiated by each successive issue of the *Journal of Analytical and Applied Pyrolysis*.

Material gain has resulted from the adoption of hyphenated instrumentation (e.g. coupling with high speed quadrupole mass spectrometry or Fourier transform infrared spectrophotometry) and has most certainly elevated the status of the technique.

Introduction

The term 'injection' encompasses techniques used to transfer samples of gases, liquids and solids on to the

column for the process of separation to take place. Sample components must be vaporized without decomposition and both major and trace components transferred quantitatively to the column, irrespective of volatility, polarity, etc. During this process, column efficiency must be preserved and band broadening arising from injection (dead space, adsorptive

sites) must be minimized. The operating conditions, e.g. column temperature and solvent used, should not influence injection, and retention times and peak areas should be reproducible.

Injectors for pyrolysis-GC and supercritical fluid chromatography will not be dealt with in this article.

Gas Samples

For accurate quantitative analysis gas samples are nearly always introduced by means of a valve fitted with an internal or external sample loop. Although the construction of gas-sampling valves takes a variety of forms, the principle of operation is common to all. In one configuration the gas passes through a loop ranging from approximately 0.1 to 10 mL in size while the carrier gas passes into the column. In the other configuration, the sample is isolated and the carrier gas stream sweeps the sample trapped in the loop onto the column. If care is taken to control the temperature and pressure of the gas, such valves offer very high reproducibility and all quantitative analysis can be performed by external calibration. They can also be readily automated for plant analysis. For further details see Gas analysis by gas chromatography. Gas samples can be injected on to columns by means of gas-tight syringes but the precision is much poorer than that with loop valves and their use is not recommended for accurate quantitative analysis.

Solid Samples

Solid samples are best dealt with by dissolving them in a suitable solvent and treating them as liquid samples. It is not always possible to find a suitable solvent or the 'sample' might be in a matrix such as soil or sand. For such materials packed columns have been fitted with capsule samplers where the capsule is dropped into a hot vaporizing zone and is withdrawn by a magnet after analysis.

Liquid Samples

The majority of samples analysed in the laboratory are in liquid form, as would be expected from the range of compounds likely to be amenable to GC. Most of this article is, therefore, concerned with the introduction of liquid samples onto packed and capillary columns.

Packed Columns

The equilibrium distribution of analyte between the two phases should be independent of sample size.

However, as sample size increases isotherms become nonlinear and peaks become broader and distorted, which leads to reduced resolution. A column is regarded as overloaded if its efficiency is reduced by 10%. The approximate maximum vapour volume (V_{\max}) of an individual solute not leading to detectable peak broadening can be calculated from:

$$V_{\max} = \frac{0.02 \times V_R}{\sqrt{N}} \quad [1]$$

where V_R is the retention volume and N is the number of theoretical plates.

For a component eluted with a retention volume of 150 mL (after 5 min at 30 mL min⁻¹) from a packed column of 3000 plates, V_{\max} is approximately 50 μ L, equivalent to 0.1 μ L liquid.

More empirically, initial bandwidth should be not more than a tenth of the width of the narrowest peak and the smaller the sample the better the chromatography. The analyst should inject microgram quantities. Since 0.1 μ L corresponds to 100 μ g for a liquid of unit density, dilute solutions are necessary if only a few micrograms are required.

Vaporizing Injector

Injection is usually performed with a syringe, through a replaceable, self-sealing plastic or rubber septum into an injector of approximately $\frac{1}{4}$ in i.d. (6 mm). The column is attached either to the base of the injector or inserted within it. In the former instance metal fittings are usually used. The injector is heated to facilitate rapid transfer of sample to the column ('flash vaporization'). To limit sample decomposition on hot metal surfaces, the injector usually contains a glass liner that can be replaced when dirty and can be regularly deactivated by silylation. The injector temperature should be high enough to vaporize the components of interest; as the temperature required to do this is rarely known, the temperature is usually set to *ca.* 50°C above the oven maximum.

The column inserted inside the injector usually reaches almost to the septum and the sample makes contact with the column only ('on-column' injection). Glass columns are installed with fittings incorporating ferrules of graphite or poly(tetrafluoroethylene) (PTFE) and these fittings must be leak-tested regularly. On-column injection can be used equally successfully for small injections of concentrated solutions or larger volumes of dilute solutions – initial band volume (of liquid) is unlikely to exceed 50 μ L. For high temperature chromatography the injector is heated and again the volume of vapour is important (unless the injector is heated after injection, when it should be confirmed that the heating rate matches that of the

column oven). The injector temperature should not exceed the maximum operating temperature of the stationary phase.

Injectors are rarely heated uniformly; the heating block encloses only part of the injector body and the rest is heated by conduction. Sometimes, to reduce septum decomposition and bleed, the injector is designed so that the septum nut is colder than the rest of the injector. Carrier gas enters the injector through an inlet in the jacket enclosing the injector liner. Usually it is warmed by passage through a coil of stainless-steel tubing wound round the injector heating block; this helps ensure that vaporized sample does not encounter cold carrier gas.

Syringes

Plunger-in-barrel (5–1000 μL) and plunger-in-needle (0.5 or 1 μL) syringes are widely available. The latter are used to dispense quantities up to 1 μL , although the 5 μL syringe can be used to dispense 0.3 μL with reasonable repeatability, especially if used on an autosampler, although the amount injected is not necessarily that indicated on the graduated scale. With the plunger-in-barrel syringe, needle volume is relevant if the injector temperature is above the solvent boiling point. When the plunger-in-needle syringe is used for vaporizing injection the needle temperature starts to increase when the needle penetrates the septum; the sample should, therefore, be partly withdrawn into the needle, otherwise part will be discharged into the septum.

It is difficult to determine the volume of sample remaining in the needle after vaporizing injection. Much will be forced from the syringe by explosive vaporization; this will cool the needle (passage of cold solution; absorption of latent heat of vaporization) and some sample will inevitably evaporate from inside the needle, depositing involatile residue. Such problems decrease in significance with increasing injection volume (but are immensely significant in capillary GC). Passage of sample through a hot steel needle can lead to decomposition of unstable sample components.

These considerations have led to the development of several different syringe-handling techniques.

Filled needle The plunger is moved quickly up and down to eject air and the syringe is removed from the sample with the plunger fully depressed. The sample is injected by pushing the syringe through the septum without moving the plunger. The needle volume only is injected, some sample is inevitably 'injected' into the septum, and much of the sample evaporates from the inner surface of the needle.

Cold needle The sample is withdrawn into the barrel and the syringe is inserted through the septum and the plunger depressed immediately. It is hoped that most of the sample passes through the needle in the liquid state with the needle still cold. Sample remaining in the needle, however, evaporates as the needle warms.

Hot needle Performed as above but the needle is left to warm in the injector for 3–4 s before rapid depression of the plunger. Much of the sample is rapidly ejected from the needle as a result of rapid explosive vaporization in the first stages of injection. The amount of sample evaporating from the inside of the needle is probably less than for cold needle injection.

Solvent flush A small volume (*c.* 1 μL) of solvent is withdrawn into the barrel, then the sample (possibly with an air barrier between the two to prevent mixing). Injection is performed by hot or cold needle injection. The sample can be sandwiched between two portions of solvent.

Air flush As above, but with air in place of solvent. However, the continuous introduction of oxygen into the column is not recommended for high temperature work because of the deleterious effect on the stationary phase.

Air and solvent As above, but with both air and solvent.

Sample Vaporization

It is not clear what happens to the sample inside the injector. Almost certainly it enters as liquid droplets. Although it is widely assumed that vaporization proceeds almost instantaneously, it is unlikely that enough energy is available, certainly in the carrier gas, to supply the latent heat required. If the liquid sample hits the wall of the injector, instant evaporation of the solvent in contact with the wall probably forces the sample away from the wall, i.e. the source of heat. Even if the sample is injected into a hot packing only a small amount of heat is available and the sample probably evaporates quite slowly.

Disadvantages

The vaporizing injector works well for packed-column injection but septa cause problems and must be changed frequently to avoid leaks. Septa also generate ghost peaks from plasticizers added for flexibility; decomposition products and delayed release of absorbed polar materials, especially if injection sizes are too large. The best solution to the problem is to

divert a small amount of carrier gas over the septum surface and to exhaust this stream to atmosphere.

Capillary Columns

Typical carrier gas flow rates for 0.3 mm i.d. wall-coated open-tubular (WCOT) columns are less than 2 mL min^{-1} . The vapour from $1 \mu\text{L}$ solvent occupies approximately 0.5 mL at 250°C . If the injector volume is 1.0 mL and flow of one injector volume of carrier gas sweeps all the vapour on to the column (no diffusion of sample with carrier gas), transfer time is $\geq 30 \text{ s}$ – considerably more than the 5 s peak widths typically encountered in capillary GC. In reality, sample concentration in the carrier gas decreases exponentially because carrier gas diffuses into the sample vapour cloud; this adds a tail to the band widths given above.

There is clearly a need for a different method of injection or a means of narrowing the band-width.

Split Injection

Split injection, or indirect sampling after vaporizing injection, was the earliest attempt to solve this problem. For many years it was the only technique available; it is still very popular.

Carrier flow through the injector is split; a small proportion is directed into the column and the remainder is vented. When the sample is vaporized a small proportion of the vapour cloud only is transferred to the column; this reduces the time during which sample is transferred into the column. The split ratio is:

$$\frac{\text{carrier flow to atmosphere}}{\text{flow through the column}}$$

Most of sample is lost so the technique is not suitable for trace analysis (sample components present at levels below 0.01%) but it is well suited for complex, relatively low-boiling mixtures, such as gasoline, containing many components in the range $0.01\text{--}10\%$.

Originally it was widely believed that the splitter eliminated the column overloading believed to be responsible for excessive bandwidths. This could have been achieved by diluting the sample. Although the capacities of capillary columns are well below those of packed columns, the effect of overloading on band broadening is negligible compared with the effect of slow sample transfer.

Using eqn [1] for a 0.32 mm i.d. column with $90\,000$ theoretical plates and a component for which V_R is 10 mL (elution after 5 min at 2 mL min^{-1})

shows that V_{max} is approximately $1 \mu\text{L}$ (equivalent to $0.002 \mu\text{L}$ liquid). This formula gives a pessimistic result for capillary columns and $15 \mu\text{L}$ is more realistic. Even so, to reduce 0.5 mL vapour to 0.015 mL requires a split ratio of $33:1$; to take account of sample diffusion in the carrier gas, practical split ratios must be considerably higher ($>100:1$).

Splitter Design Features

Splitting should be reproducible; reproducibility is, however, affected by many factors.

The sample must encounter inert surfaces only – the injector usually contains a glass liner. Splitting should be linear and nondiscriminatory, i.e. sample should be vaporized rapidly and pass the column inlet as a concentrated, homogeneous plug. Because of the limited heat available, the sample is unlikely to be vaporized instantaneously. Droplets can be carried into the column irreproducibly and evaporation of droplets in the injector leads to fractional distillation. Such behaviour can be overcome by using a mixing device, e.g. packing the liner with glass wool or glass beads. This can cause dilution of the sample (loss of sensitivity) and discrimination owing to adsorption, condensation and decomposition. Adsorption can be reduced by silylation *in situ* (because packing an injector with silylated glass wool results in fracture of the glass fibres and exposure of new active sites); condensation might be eliminated by increasing the temperature.

Packed injector liners were introduced as thermal reservoirs to encourage rapid vaporization. Calculations show, however, that except for volumes of *ca.* $0.5 \mu\text{L}$, the amount of heat available from carrier gas and liner packing is well below that required for vaporization. Heat is available from the injector wall, but when solvent droplets touch this they are instantly repelled by vaporization of the small amount of solvent in (instantaneous) contact with the wall. It is now accepted that the packing provides a surface that retains the entire sample during slow, controlled evaporation.

The carrier gas is heated so that at high split ratios the gas flow does not cool the injector, leading to variation in the split ratio or incomplete volatilization. If the vent flow is turned off after injection (to conserve carrier gas), ensure: (1) this does not affect column head pressure, hence carrier gas flow rate (back-pressure regulation is claimed to achieve this); (2) there is a small continuous flow from the injector to eliminate back diffusion of partially vented material; and (3) the injector septum is gently purged to atmosphere to eliminate ghost peaks from septum bleed.

It has been suggested that a buffer volume beyond the split point reduces pressure fluctuations that might lead to variations in carrier flow and split ratio; although such buffer volumes do indeed help dispel pressure waves, their benefits have been disputed.

Injection Technique

The most reproducible injections with least discrimination are given by the 'hot needle' (1.5–2 μL) and 'solvent flush' techniques. Needle-in-plunger syringes cannot be used because samples start to evaporate as soon as the syringe enters the injector, leading to fractionation and discrimination. Injector temperature should be near the boiling point of the sample's least volatile components or discrimination might arise even from a well-designed splitter, especially at low (<100:1) split ratios. If it is essential to use a low split ratio, e.g. in trace analysis, then a high temperature must be used. For unstable compounds a low injector temperature and high split ratio are desirable.

If the column temperature is below the solvent boiling point and the solvent vapour pressure is sufficiently high (depending on injection size and split ratio), sample can condense in the column. The resulting sudden drop in pressure leads to suction of material from the injector and the split ratio will vary. Similar effects might lead to condensation in gas lines control valves, etc., leading to ghost peaks later in the analysis as the material diffuses back into the injector.

The column should be mounted with its inlet at, or near, the injector base to minimize the volume from which back-diffusion might occur. For the largest signal, needle length should be such that sample is released at the column inlet (10 mm gap). The effect of needle length on response should be checked experimentally.

It is worth varying the split ratio over a wide range – a high split ratio might result in such rapid flow through the injector that the sample passes the column inlet while still in the form of a concentrated plug. The vapour cloud concentration can be optimized to prevent back-diffusion by use of an injector liner compatible with injection. For low split ratios (10:1–50:1) and 8 cm liner typical values are: a 1.5 mm i.d. liner for 0.4 μL injection, a 2.0 mm i.d. liner for 0.6 μL injection, and a 3.5 mm i.d. liner for 2.0 μL injection.

Advantages and Disadvantages

The advantages of the splitter are simplicity – for qualitative and semiquantitative work very little can go wrong. Its major disadvantage is discrimination: inhomogeneous mixing of carrier gas and sample and

different rates of evaporation and incomplete evaporation of components of different volatility inside the syringe needle and from droplets in the injector body. Other disadvantages include unsuitability for temperature-sensitive and involatile compounds and low sensitivity for trace analysis. Condensation of solvent inside the column, pressure surges on injection and changes in the volumes of carrier and sample gases on moving from injector to oven at different temperatures reduce reproducibility and mean that the actual split ratio is never that calculated from gas flow rates. To minimize errors from these effects, the operating conditions must be kept as constant as possible and internal standards should be used for quantitative analysis. Venting most of a sample to atmosphere may represent a safety hazard.

Reconcentration of Bands Broadened by Split Injection

Cold trapping If the difference between the column temperatures at injection and elution is $>45^\circ\text{C}$ (approx.), then material of low volatility is retained by the cold column and migrates only a small distance before transfer from the injector is complete; it starts to migrate only when the oven temperature is increased. The extent of reconcentration depends on the ratio of the migration rates of the volatile and involatile components. Because the migration speeds of most components are halved if the temperature is reduced by 15°C , there is a concentration factor of 2 for each 15°C difference between the column temperatures at injection and elution. A difference of 80°C will always render any band broadening resulting from injection undetectable and in normal circumstances a difference of 40 – 60°C will be sufficient.

Splitless Injection with Solvent Trapping

If solvent is injected by vaporizing injection into a column maintained at a temperature below the solvent boiling point, the vapour leaving the injector will, under certain conditions, condense in the column inlet. Splitless injection incorporating solvent trapping exploits this behaviour. The injector used is similar in design to some splitters (**Figure 1**), in that it has outlets to the column and splitter and a septum purge. During injection and for a short time afterwards (so-called 'splitless period') the injector and (often) septum purge vents are kept closed and the only exit from the injector is onto the column. At other times the vents remain open.

The injector vent is for rapid removal from the injector of material not reaching the column during

Figure 1 The split-splitless injector.

the splitless period. The vent flow is set to 20–100 mL min⁻¹. The purpose of the septum purge (1–2 mL min⁻¹) is as described above.

For injection, the oven temperature is set to $\leq 20^\circ\text{C}$ below the solvent boiling point (the optimum temperature is best determined experimentally), the vents are closed and the sample (1–2.5 μL) injected. After the splitless period (20–60 s) the vents are opened and chromatography initiated. The condensed solvent in the column acts as a thick layer of stationary phase, which dissolves the sample's components. Carrier gas passing over the film is rapidly saturated with solvent vapour so all solvent evaporation occurs at the rear of the film. As the length of the solvent film decreases, sample components remain in solution in the narrowing band of liquid. When the last trace of solvent evaporates, the sample components will have been concentrated into a narrow band from which to start chromatography.

Exploitation of solvent trapping is not limited to injection of liquids. If 2–3 μL solvent is condensed in the column inlet it can be used to trap volatile organic compounds injected as a vapour immediately afterwards (i.e. before the solvent has evaporated). This could be useful for headspace analysis.

Injection Technique

Initial vaporization of the sample is identical with that in split injection and so many of the factors described above are relevant. The text below covers points of special relevance to obtaining satisfactory solvent trapping.

The solvent boiling point should be 20°C below the column temperature at the start of chromatography.

Because, irrespective of oven temperature, the solvent will condense quantitatively only if its vapour pressure is sufficiently high, the amount of solvent injected must be adequate (1–2.5 μL is usually sufficient); excessive dilution of the sample vapour cloud with carrier gas should be eliminated by use of an injector liner of appropriate volume. If the solvent boiling point is too high the solvent peak might interfere with those of the sample components, although this might be overcome by choosing a solvent only sparingly soluble in the liquid phase and thus eluted quickly.

To reduce discrimination against less volatile sample components 90–95% of the sample must be transferred to the column. Because of dilution of sample in the injector, such transfer requires a splitless period four times that necessary to transfer undiluted sample; this could lead to excessive solvent tailing. In practice, the pressure drop caused by solvent condensation results in sample being sucked into the column faster than would otherwise occur; this offsets band broadening caused by sample dilution such that it is rarely a problem for sample volumes $< 4 \mu\text{L}$. The optimum splitless period should be determined experimentally, starting at *ca.* 20–30 s and increasing it for larger volumes and less volatile compounds. Optimum column position, needle length, etc., must also be determined experimentally.

If the injector has a separate septum purge and its flow is maintained sufficiently low, it may be possible to leave it open during injection without significant loss of sample, thus almost eliminating the effects of septum bleed.

Advantages and Disadvantages

The technique is reasonably simple, and applicable to dilute samples, trace analysis and to volatile and involatile compounds; it is reasonably good for quantitative analysis. Because the sample can be transferred to the column over a longer period than is possible for split injection, the injector can be maintained at a lower temperature, rendering the technique more suitable for the analysis of thermally unstable compounds.

In addition to the usual disadvantages of vaporizing injection (e.g. discrimination), solvent condensation leads to several extra problems including peak distortion and peak splitting. These can be overcome by employing a 'retention gap' (an uncoated pre-column) and by using solvents that wet the stationary phase (rather than forming droplets) and in which all the sample components are highly soluble; the volume injected should be as low as possible. Solvent condensation can lead to damage of very polar stationary phases (which are less well immobilized). The

solvent film can also result in variations in retention data, especially for different solvent volumes.

Cold On-Column Injection

This term denotes direct transfer of liquid sample into the column inlet, i.e. the sample is introduced to the column as a liquid rather than being evaporated from the syringe. Because the technique exploits solvent trapping, the column inlet must be kept cool, i.e. 10°C below the solvent boiling point (cf. 20°C below for splitless injection). In this way explosive evaporation of sample does not lead to its being flushed back into the cold injector where it might be lost completely or from where it might slowly drift back on to the column, leading to band broadening. The point of injection must, however, be positioned within the temperature control of the oven, usually 5–10 mm from the oven wall (a greater distance increases the chance of the needle being heated). The original design had the injector body only cooled. Later versions had the addition of secondary cooling so that during injection the section of column in the oven, and into which injection took place, could be cooled, thus increasing the range of temperatures over which the technique could be used. The injector body should be isolated from the hot insulating material of the oven top.

Injection is performed with a special syringe with a needle of o.d. 0.05 mm less than the column i.d. (so it does not plug the column and restrict carrier gas flow. The syringe is inserted into the column via a seal that prevents escape of carrier gas (column head pressure should be maintained). The carrier gas line to the injector should be through wide-bore tubing so that any slight leakage through the needle-seal does not affect the column head pressure. For borosilicate columns needle entry into the column is aided by chamfering the column inlet. This is not possible with fused silica because the column wall is too thin.

Injection speed depends on the injector. Better quantitative results are obtained by rapid injection, sending the sample well into the column to reduce the possibility of sample adhering to the needle and being removed when the syringe is withdrawn. Reproducible injection of 0.5–8 µL is possible. Smaller quantities are more difficult because they cannot be measured accurately with a 5 or 10 µL syringe and the speed at which the sample is ejected from a 0.5 or 1 µL syringe is insufficient to carry the sample well away from the syringe needle. If fast injection of these sample volumes is performed at oven temperatures near the solvent boiling point there are no problems with expanding clouds of solvent vapour being forced

back past the syringe needle (with consequent sample loss). At higher temperatures it is essential that the injector is fitted with secondary cooling so that sample is ejected into a cool section of the column. If secondary cooling is not available, it might be necessary to inject slowly at or about the solvent boiling point so that the vapour formed on evaporation from the column wall (not from the syringe needle) is carried away as it is formed. Some loss on the needle usually accompanies this technique, but losses are less than if the sample were to be forced explosively back into the injector body. Losses might be reduced by increasing the carrier flow and/or leaving the syringe in the injector for a few seconds after injection, to promote evaporation of the more volatile materials. However, this technique will lead to discrimination of another type, especially if the syringe needle becomes warm. Typical speeds for slow injection of different volumes of pentane are: 0.125 µL, 0.5 s; 0.5 µL, 1 s; 2 µL, 5 s; 8 µL, 20 s. If injections are much slower than this the solvent vapour pressure might be insufficient for condensation and no solvent trapping will occur. For volumes less than 0.2 µL rapid injection can be performed without secondary cooling, as the amount of vapour produced is insufficient to cause the sample to be expelled backwards.

In addition to cold trapping, which with on-column injection is effective for injections as small as 0.1 µL (cf. 0.5–1 µL for splitless injection), cold-trapping can also be exploited. Because cold trapping is less effective than solvent trapping the difference between elution and injection temperatures should be 80–120°C if effects are to be comparable.

Advantages

Quantitation and reproducibility are excellent and discrimination is negligible; the technique is ideal for heat-sensitive and low volatility materials that would not reach column if subjected to vaporizing injection. Vaporizing injectors perform very poorly with samples containing large amounts of involatile material, owing to irreproducible entrapment of volatile compounds.

Disadvantages

Insertion of the needle into the column can cause perturbations in carrier flow. The technique is susceptible to the peak splitting and solvent effects observed with splitless injection. Large amounts of solvent affect retention behaviour (cf. splitless injection) and can damage the column if an immobilized phase is not used (rare nowadays). The technique results in involatile sample components being deposited on the column; this can be overcome by washing the column

(the whole column if immobilized, the column inlet if not), removal of the column inlet, and/or use of a pre-column.

Programmed-Temperature Vaporizing Injector

Originally regarded as a means of injecting solids, the programmed-temperature vaporizing (PTV) injector is now seen as a means of overcoming problems associated with the hot needle in conventional vaporizing injectors. The sample is injected into a cooled injector body, which is then ballistically heated (at $10\text{--}30^\circ\text{C s}^{-1}$, possibly with several ramps and plateaux) to the required temperature (e.g. to 300°C in 20–30 s).

Design Features

The narrow (0.5–1.5 mm i.d., volume 15–150 μL), low thermal-mass injector liner ensures rapid heating and fast carrier flow. The insert is packed to retain sample droplets and, because the packing is fairly dense (for good thermal conduction), there is a seal between liner and injector body to ensure carrier passes through the liner. The packing can be glass fibre or beads for low retention (e.g. analysis of involatile materials), or porous materials such as Chromosorb (possibly coated with liquid phase) for greater retention. There is a facility for rapid cooling (e.g. by air flow) before injection, and the heater control can include a low temperature thermostating option for selective solvent removal. The septum is usually kept permanently cold, otherwise construction is similar to that of conventional vaporizers.

Advantages

This technique is useful for large volumes (10–50 μL , even 1 mL), especially if solvent vapours are vented to atmosphere before the remaining sample is directed on to the column. This is especially useful for analysis of high boiling solutes (sometimes called split-splitless injection or solvent-split injection), but results in loss of volatile compounds (possibly up to C_{20}). The vapour cloud from the solvent injected must not be so great that it flows back from the injector insert. To some extent this can be achieved by careful injector heating. Needle-in-plunger syringes can be used for small injections (injector not hot).

The PTV injector is useful for both split and splitless injection. Solvent trapping can be achieved with the latter but can often be avoided by adjusting the timing. Heating should be fast so that volatilization occurs quickly, especially if chromatographic migration starts immediately (i.e. no cold trapping

or solvent trapping), but this might cause thermal degradation.

The narrow liner means high carrier gas flow, so transfer to column is fast; retention by packing can be tolerated as carrier flow partially compensates (less likelihood of problematical matrix effects with dirty samples). Shorter transfer periods can be used for splitless injection; the use of lower column flow rates than for conventional split or splitless injection can still result in good transfer. The technique gives good precision because there is no aerosol formation and diffusion of quickly flowing carrier gas with sample means little recondensation of solvent in the column in split or solvent-splitless injection. There is no pressure wave, and less chance of matrix effects with dirty samples. Finally, there are no unwanted solvent effects with split or solvent-split injection.

Disadvantages

The rules for operation (e.g. injection speed, timing of heating and venting) are complicated and care is needed with timing of heating. Labile solutes, especially involatile materials requiring long transfer periods (high molecular weight triacylglycerols), are subject to thermal stress. The injector liner is too small for headspace samples. Transfer is by fractionation and any slight change in split ratio will result in components of different volatility being split by different ratios, probably irreproducibly.

Because of the small volume of the insert, the conventional PTV injector could not originally double as a split-splitless injector; this has been overcome by the introduction of an injector incorporating innovative heating technology that enables the size of the PTV to be increased to that of conventional vaporizing injectors. This injector can also be used for analysis of gases and solids. If the liner is packed with an adsorbent it can be used, either *in situ* or temporarily removed from the injector, to adsorb volatile organic compounds.

Cooled-Needle Vaporizing Injector

This injector was designed specifically to overcome problems associated with the hot syringe needle. It comprises a standard vaporizing injector with a glass insert. Between the septum and the upper region of the heated part of the injector body (and inserted into the upper region of the insert) is a gas-cooled jacket of length accommodating the needle of a standard syringe – when the needle is inserted only a millimetre protrudes into the heated region of the injector. After injection the syringe is removed and the cooling gas turned off. The base of the cooling jacket then heats

up so that material coming into contact with it might be vaporized. The technique should ensure minimization of discrimination caused by selective fractionation from the syringe needle. Published results seem to confirm that the technique gives highly precise quantitative results.

Conclusion

For many years the introduction of sample into the column represented the weak point for accurate quantitative analysis by capillary columns. In the last few years this has largely been remedied and good quantitation can be achieved by the use of one of the range of commercially available injectors. However, it was pointed out by Deans a number of years ago

that the only completely reliable method of sample introduction was in the vapour phase, i.e. handling all samples as gases. While this might be true, it is something of a council of perfection and it is likely that syringe injection through a septum will be with us for the foreseeable future.

Introduction

Gas chromatography (GC) involves the separation of the components of a mixture by virtue of differences in the equilibrium distribution of the components between two phases; the gaseous (mobile) phase moves in a definite direction, while the other phase is stationary (stationary phase).

Stationary Phase

In gas-liquid chromatography (GLC) the stationary phase is a liquid coated onto a solid support, which may or may not contribute to the separation process, or onto the walls of an open tube. The liquid may also be chemically bonded to the solid or capillary tube (bonded phase) or immobilized on it, e.g. by *in situ* polymerization (cross-linking) after coating (immobilized phase). In gas-solid chromatography (GSC) the stationary phase is an active solid (e.g. silica, alumina or a polymer). Gas chromatography is always carried out within a tube and the combination of stationary phase and tube is referred to as the column (column chromatography). The stationary phase (liquid + support) may fill the whole inside volume of the tube (packed column) or be concentrated along the inside wall of the tube, leaving an unrestricted path for the mobile phase in the middle of the tube (open-tubular or capillary column).

In open-tubular columns, the liquid stationary phase can be coated onto the essentially unmodified

smooth inner wall of the tube (wall-coated open-tubular (WCOT) column). The inner wall may be made porous by etching the surface by chemical means or by depositing porous particles on the wall from a suspension, the porous layer acting as the stationary phase or as a support for a liquid (porous-layer open-tubular (PLOT) column); or the porous layer may consist of support particles deposited from suspension (support-coated open-tubular (SCOT) column). The term capillary column denotes a column (packed or open-tubular) having a small diameter.

With a solid stationary phase, separation is based mainly on adsorption affinities between the sample molecules and the surface of the active solid (adsorption chromatography). With a liquid stationary phase separation depends on the solubilities of the sample molecules (partition chromatography). In keeping with other partition processes, the sample molecules are often referred to as the solute and the stationary phase as the solvent. This terminology is acceptable in gas chromatography, but can cause confusion in liquid chromatography.

Mobile Phase

In GC at normal pressures (1–2 atm; $1\text{--}2 \times 10^5$ Pa) the mobile phase (usually called the carrier gas) plays little, if any, part in the separation, but only serves to carry the sample molecules through the column.

The time taken by a sample in passing through the column (the total elution/retention time, t_R) is a function of the carrier gas velocity, and the volume of carrier gas required to elute the component from the

column, the total retention volume (V_R), is given by: moves at the same velocity as the mobile phase:

$$V_R = F \times t_R$$

$$\bar{u} = L/t_M$$

where F is the volume flow rate of carrier gas measured at the column outlet at ambient temperature (T_a) and ambient pressure (p_a). If a water-containing flow meter (e.g. the soap bubble flow meter) is used, the measured flow rate must be corrected to dry gas conditions to give the mobile phase flow rate at ambient temperature (F_a):

$$F_a = F(1 - p_w/p_a)$$

where p_w is the partial pressure of water vapour at ambient temperature.

The mobile phase flow rate (F_c) at the column temperature (T_c , Kelvin) is:

$$F_c = F_a(T_c/T_a)$$

To achieve a flow rate through the column, the inlet pressure (p_i) of carrier gas must be greater than the outlet pressure (p_o), the difference being the pressure drop (Δp).

Gases are compressible fluids, and in order to correct for this flow rate measurements a correction, the mobile phase compressibility correction factor (j), has to be used. Thus:

$$j = \frac{3[(p_i/p_o)^2 - 1]}{2[(p_i/p_o)^3 - 1]}$$

It is easiest to measure the volume flow of the carrier gas through the column, but for many purposes the linear flow rate (\bar{u}) is required. The linear velocity across the average cross-section of the chromatographic column can be calculated from the flow rate at column temperature (F_c), the cross-sectional area of the column (A_c) and the interparticle porosity (ϵ):

$$\bar{u} = F_c/(\epsilon A_c)$$

where the interparticle porosity is the interparticle volume of a packed column per unit area. For an open-tubular column this term is equal to 1.

Since the flow rate at column temperature (F_c) is measured at the outlet, in GC the carrier gas velocity at column outlet (u_o) is frequently employed. Correcting this term for gas compressibility gives the average linear carrier gas velocity (\bar{u}) = $u_o j$.

In practice, the average linear carrier gas velocity is calculated by dividing the column length (L) by the retention time (t_M) of an unretained peak, i.e. one that

Methods of Chromatography

In most analytical applications of GC the mobile phase is continuously passed through the column and the sample is fed (or injected) into the system as a finite plug. This process is known as *elution chromatography*. If the conditions for the analysis are optimized the sample components can be separated completely from each other. If the sample is fed continuously onto the column with no added mobile phase, the process is known as *frontal analysis*. Only the first component to emerge from the column may be obtained pure, the other components being contaminated with earlier emerging components. A third technique, used occasionally in liquid chromatography (LC) but rarely in GC, is *displacement development*, which uses a strongly sorbed mobile phase to push (or displace) the components off the column. Each component can be obtained pure, but there is overlap between adjacent components placing a detector at the end of the column, which responds to some property of the sample molecules, produces a trace (the chromatogram) that is a plot of detector response against time.

The General Elution Problem

A typical chromatogram for the separation of a mixture of components is shown in **Figure 1**. This illustrates the characteristics of chromatography, often referred to as the 'general elution problem'. The properties illustrated by the chromatogram, which must be explained by any theory of chromatography, are:

- the components of the mixture elute from the column at different times (retention);
- peak widths increase with retention time (peak shape and broadening);
- the separation of pairs of peaks is not constant (column resolution).

Chromatographic Retention

Retention parameters are measured in terms of chart distances or times, mobile phase volumes or retention factors (k) (previously called capacity factors, k'). With a constant recorder speed, chart distances are directly proportional to times. Likewise if the flow rate is constant, the volumes are proportional to times, e.g. t_R (time) is analogous to V_R (volume). In GC with a compressible carrier gas, V_M , V_R and V'_R represent volumes under column outlet pressure.

Figure 1 The general elution problem.

If F_c is used in their calculation these correspond to volumes at column temperature.

When a mixture is chromatographed, the time taken for a component to be eluted from the column, the (total) retention time (t_R), is measured from the moment of injection to the appearance of the peak maximum. This, together with the width of the peak measured at the baseline (w) or at half peak height (w_h), and the elution of an 'unretained peak', are important parameters in chromatography. These are illustrated in Figure 2, which represents the separation of a two-component mixture.

The retention volume (V_M) of an unretained peak (where $V_M = F \times t_M$) is also called the gas hold-up volume or dead volume, and is equal to the volume (both inter- and intra-particle) available to the mobile phase in the column. The corrected gas hold-up volume (V_M^0) is corrected for gas compressibility where $V_M^0 = V_M j$.

Injection techniques in GC, where the sample is held at the head of the column before it starts moving through the column, have necessitated the introduction of additional terms. These are the peak time/volume (t_R, V_R), where the time/volume is measured from the start of elution rather than time of injection, and the adjusted retention time/volume (t'_R/V'_R), which is the total elution time/volume minus the gas hold-up time/volume:

$$t'_R = t_R - t_M; \quad V'_R = V_R - V_M$$

The corrected retention time/volume (t_R^0/V_R^0) is the total retention time/volume corrected for carrier gas compressibility:

$$t_R^0 = t_R j = V_R j / F_c = V_R^0 / F_c; \quad V_R^0 = V_R j$$

The net retention time/volume (t_N, V_N) is the adjusted retention time/volume corrected for carrier gas

Figure 2 Separation of a two-component mixture showing retention parameters.

compressibility:

$$t_N = V'_R j / F_c = V_N / F_c; \quad V_N = V'_R j$$

The specific retention volume at column temperature θ (V_g^θ) normalizes the retention for the amount of stationary phase on the column (W_s):

$$V_g^\theta = V_N / W_s$$

Normalizing the specific retention volume to 0°C (273.15 K) gives rise to the specific retention volume at 0°C (V_g):

$$V_g = V_g^\theta \times \frac{273.15 \text{ K}}{T_c} = \frac{V_N}{W_s} \times \frac{273.15 \text{ K}}{T_c}$$

where T_c is the column temperature.

The unretained peak is given by a substance that has no affinity for the stationary phase and therefore passes through the column at the same speed as the mobile phase. A substance that shows affinity for the stationary phase moves through the column more slowly than the mobile phase and is said to be retained. The ratio of the two velocities is known as the retardation factor (R):

$$R = \frac{\text{rate of movement of retained peak}}{\text{rate of movement of mobile phase}}$$

A retained component spends time in both the mobile phase (t_M) and the stationary phase (t_s), and retention time t_R is given by:

$$t_R = t_M + t_s$$

The time spent in the stationary phase is dependent on the distribution coefficient (K_c) such that $t_s = K_c V_s$. If C_s and C_M are the concentrations of a component in the stationary phase and mobile phase, respectively, then the distribution constant is given by:

$$K_c = C_s / C_M$$

The rate of movement of a component through the column is inversely proportional to the distribution constant, i.e. a substance with a high concentration in the stationary phase (a high distribution coefficient) moves slowly through the column. Components of a mixture are, therefore, separated only if their distribution coefficients differ. Using volumes rather than times we can write:

$$V_R = V_M + K_c V_s \quad \text{or} \quad V'_R = K_c V_s$$

which is the fundamental equation for chromatography, neglecting the effects of nonlinearity of the sorption isotherm and band broadening.

Since, in general, migration of the solute through the chromatographic column depends upon the equilibrium distribution of the solute between the stationary and mobile phases, retention is controlled by those factors that affect the distribution. In GLC, the distribution is essentially that for a two-component system; the sample (or solute) and the stationary phase (or solvent) (or the adsorbate and adsorbent respectively in gas-solid chromatography). The distribution then is a result of the molecular forces between the sample and the stationary phase and the effect of temperature and pressure on these interactions, although at the pressures normally used in GC the effect of pressure is negligible. All such forces are electrostatic in origin and are based on Coulomb's laws of attraction and repulsion between charges. The major forces involve those between charged ions (e.g. in ion chromatography), i.e. dipole-dipole interactions, dipole-induced dipole interactions, dispersion forces and hydrogen bonding forces. Dispersion forces are present in all atoms and molecules, but the other interactions depend on structural features in the molecule, i.e. ions (e.g. Cl^-), polar functional groups (e.g. C-Cl, C-OH) and polarizable groups (e.g. aromatic and conjugated molecules).

In this case of GLC, assuming that the concentration of the sample (or solute) molecules in the mobile (gas) phase is very small, as is the case if small volume sample injections are made, then the solution of solute in the stationary phase may give rise to an 'ideal solution', and the vapour pressure (p) of the solute above the solution is given by Raoult's law:

$$p = p^\circ x$$

where p° is the vapour pressure of the pure liquid solute and x is the mole fraction of the solute in solution. To correct for the 'nonideality' of real solutions, Raoult's law must be written:

$$p = \gamma p^\circ x$$

where γ is the activity coefficient at infinite dilution. The distribution coefficient (K) for the sample in the stationary phase is given by:

$$K = \frac{RT_c}{M_s \gamma p^\circ}$$

where T_c is the column temperature and M_s the molecular weight of the stationary phase. For two solute

molecules (1, 2) with distribution coefficients K_1 and K_2 , activity coefficients γ_1 and γ_2 and vapour pressures p_1° and p_2° , we can write:

$$\frac{K_1}{K_2} = \frac{\gamma_2 p_2^\circ}{\gamma_1 p_1^\circ}$$

For solutions that approximate to ideal behaviour, $\gamma \sim 1$ and the separation depends on differences in the vapour pressures; this is the case with nonpolar solutes in a nonpolar stationary phase. The existence of polar interactions between the solute and stationary phase molecules introduces nonideality into the system and $\gamma \neq 1$. This can be made use of to provide a separation. A good example is the separation of benzene (C_6H_6) and cyclohexane (C_6H_{12}), which have boiling points of 353.2 and 353.8 K, respectively. In a nonpolar stationary phase the predominant molecular interactions, between benzene or cyclohexane and the stationary phase, will be dispersion forces, and the activity coefficients for both solutes are ~ 1 . Because the difference in the vapour pressures is small, little separation is observed and the solutes are eluted from the stationary phase in order of their boiling points, i.e. benzene is eluted before cyclohexane. If a polar stationary phase is used, cyclohexane, because of its saturated nature, still only exhibits dispersion interactions and $\gamma \sim 1$. However the π electrons in benzene cause it to undergo dipole-induced dipole interactions, leading to a decrease in γ and an increase in its distribution coefficient. Hence in a polar stationary phase benzene is eluted some time after cyclohexane.

The relationship between retention and molecular structure has long been used in GC as an aid to the assignment of chromatographic peaks. Many homologous series of compounds show a linear relationship between \log (retention) and boiling point or carbon number. Since different solute types (e.g. n -alkanes, n -alkyl alcohols, n -alkyl esters) give different linear relationships with different slopes, these plots can be used to assign a chromatographic peak to a particular class of compound and to determine its carbon number and boiling point. These relationships have also been used to provide data in the form of a Retention Index as an aid to peak identification. However, with the widespread use of mass spectrometer detectors these techniques are used less than formerly.

In adsorption chromatography the stationary phase volume is replaced by the surface area (A_s) of the stationary phase, and the distribution coefficient is replaced by the adsorption coefficient (K_A). In GC both V_R and V_M have to be corrected for gas compressibility.

An alternative expression (the retention factor, k) for the distribution of a sample component is in terms

of the relative number of moles (n) of a component in the stationary and mobile phases, such that:

$$k = n_s/n_M = K_c(V_s/V_M)$$

The ratio V_s/V_M is the phase ratio. Early literature will refer to the retention factor as the capacity ratio (k').

Since a sample molecule only migrates through the column when it is in the mobile phase, the retardation factor (R) may be written:

$$R = \frac{\text{amount of solute in the mobile phase}}{\text{amount of solute in mobile + stationary phases}}$$

or:

$$R = n_M/(n_M + n_s) = 1/(1 + k)$$

Substituting the retention factor into the equation:

$$V_R = V_M + K_c V_s$$

gives:

$$V_R = V_M(1 + k)$$

or using retention times:

$$t_R = t_M(1 + k)$$

and on rearrangement:

$$k = (t_R - t_M)/t_M$$

This last expression is widely used as a simple way of expressing retention from values easily measured from the chromatogram, and without the need to measure flow rates. Since:

$$t_M = L/\bar{u}_M$$

we can write:

$$t_R = \frac{L}{\bar{u}}(1 + k)$$

Hence the retention time is directly proportional to the column length and inversely proportional to the linear flow rate of the mobile phase.

Peak Shape and Broadening

The variation of solute concentration in the stationary phase with solute concentration in the mobile phase, at constant temperature, is known as the sorption isotherm. Simple chromatographic theory

assumes a linear isotherm relationship, i.e. the distribution coefficient is constant. Under these conditions the retention time is independent of sample concentration and the peak moves with a constant speed. Given a peak profile with plug-shape distribution on injection, this plug shape should be maintained as the peak passes through the column to emerge at the exit. However, because of longitudinal diffusion in the direction of flow, the peak takes on a Gaussian distribution. If the isotherm relationship is nonlinear (e.g. Langmuirian or anti-Langmuirian), the distribution coefficient is not constant but varies with solute concentration and there is a distribution of solute molecule velocities across the peak that is described as tailing or fronting. This relationship between isotherm shape and peak shape is illustrated in Figure 3.

The width of a chromatographic peak is a function of the column efficiency, expressed as the plate number (N), calculated from the following equations depending on the value used for the peak width (see Figure 2):

$$N = (V_R/\sigma)^2 = (t_R/\sigma)^2 = 16(t_R/w_b)^2 = 5.545(t_R/w_h)^2$$

where σ is the standard deviation of the Gaussian peak.

The column length divided by the plate number gives the plate height or height equivalent to one theoretical plate (H) and normalizes the plate number for column length:

$$H = L/N$$

The concept of 'plates' in chromatographic theory (the plate theory) is by analogy with the distillation process and represents the notional length of the column in which the solute molecules reach a distribution equilibrium. Thus a large number of theoretical plates corresponds to an efficient column.

Consideration of the chromatographic process as controlled by equilibrium gives a satisfactory explanation of chromatographic retention in term of the distribution coefficients. However when considering band broadening a different approach is required, known as the rate theory of chromatography. This was first applied by van Deemter, Klinkenberg and Zuiderweg to packed columns, but has been extended and modified to include open-tubular columns.

As the solute band passes through the column the bandwidth increases and the solute is diluted by the mobile phase. Although the process of fluid flow is complex, three main contributions to band broadening (i.e. to the variance (σ^2) of the Gaussian peak) may be recognized in GC: the multipath effect, A (formerly called eddy diffusion); molecular diffusion, B ; and mass transfer, C . These contributions have been combined by van Deemter and co-workers in the van Deemter equation, which expresses the broadening of a band in terms of the plate height, H , and the average linear velocity (\bar{u}) of the mobile phase:

$$H = A + B/\bar{u} + C_s\bar{u}$$

A plot of H versus \bar{u} is shown in Figure 4. The relationship highlights the importance of using the correct flow rate for minimum H values (maximum

Figure 3 Isotherm shape and its effect on peak shape and retention times.

Figure 4 The 'van Deemter' plot and determination of the constants A , B and C_s .

N values) and allows values of A , B and C_s to be calculated as shown.

The multipath effect Molecules flowing through a packed bed of stationary phase will take paths of different lengths, resulting in a small difference in retention times. This has the effect of broadening the band by an amount dependent on the particle diameter (d_p), such that:

$$A = 2\lambda d_p$$

The packing constant (λ) is an empirical term depending on the shape (spherical or irregular) of the packing material and the packing efficiency, and reaches a minimum value $\cong 0.5$. For open-tubular column there is no 'A' term.

Longitudinal molecular diffusion Solute molecules diffuse in a longitudinal direction (i.e. along the column axis) according to Fick's law of diffusion. The amount of band spreading is directly proportional to the coefficient of diffusion (D_M) of the solute molecules in the mobile phase, and inversely proportional to the mobile phase flow rate. An obstruction factor (ψ) is introduced to account for the restricted diffusion in a packed bed. Hence:

$$B = 2\psi D_M / \bar{u}$$

Mass transfer In GC the only form of mass transfer that is significant involves the movement of the solute molecules in and out of the stationary phase (stationary phase mass transfer, C_s). At the head of the column the solute is distributed between the stationary and mobile phases according to the value of the distribution coefficient. As the band moves down the column, solute at the leading edge of the band is

continually meeting new stationary phase into which it dissolves. To maintain the equilibrium, solute will move from the trailing edge of the band, out of the stationary phase back into the mobile phase. Because this process is not instantaneous, the band is broadened. A fast-moving mobile phase sweeps the zone more rapidly through the column and accentuates the band broadening, as does a greater film thickness (d_f) of stationary phase. A higher rate of solute diffusion in the stationary phase (D_s) will decrease the band broadening, so that:

$$C_s = q \times \frac{k d_f^2 \bar{u}}{(1+k)^2 D_s}$$

where q is a configuration factor depending on the nature of the stationary phase. In adsorption chromatography the C_s term is expressed in terms of the adsorption/desorption kinetics of the solute molecules on the stationary phase.

van Deemter type plots using different carrier gases show that although nitrogen gives slightly lower H values, this is only achieved at relatively low flow rates ($\sim 15 \text{ cm s}^{-1}$), and as the flow rate increases the value of H increases rapidly. Hydrogen has a much flatter curve and is best for fast analysis with high flow rates (above 30 cm s^{-1}). Because of the inherent safety problems from hydrogen, helium is a good compromise and is used in most coupled techniques (e.g. gas chromatography-mass spectrometry, GC-MS).

A modernized version of the van Deemter equation includes the multipath term (A) in a more generalized term covering mass transfer in the mobile phase (C_M):

$$H = B/\bar{u} + C_s \bar{u} + C_M \bar{u}$$

where:

$$C_M = f(d_p^2, \bar{u})/D_M$$

Open-tubular columns are often evaluated by comparing the theoretical maximum number of plates with that of the actual calculated number of plates, where:

$$H(\text{min}) = r_o \frac{1 + 6k + 11k^2}{3(1+k)^2}$$

and r_o is the column radius.

Extra-column band broadening So far we have only considered band broadening processes within the chromatographic column itself, but in assessing the overall performance of the system the instrument as a whole is important. Thus the injection system,

detector and connecting tubing all contribute to the overall analysis. The objective for the injection is to vaporize the sample onto the column in as narrow a plug as possible; slow vaporization or the existence of zones unswept by mobile phase in the injector will lead to both band broadening and peak tailing. Large dead volumes in the detector can lead to remixing of components and deterioration of the separation as well as dilution of the sample peaks, thus reducing detection limits. Generally the design of gas chromatographs eliminates the need for long lengths of connecting tubing, often a major problem in liquid chromatographs.

Column Resolution

Chromatographic separation is only achieved when there is a difference in the distribution coefficients of two components, i.e. the molecular interactions (dispersion forces, dipole interactions and hydrogen bonding forces) between the sample molecules and the stationary phase are sufficiently different. More fundamentally it is the free energies of distribution $\Delta(\Delta G^\ominus)$ of the components of a mixture that must differ. It can be shown that:

$$\Delta(\Delta G^\ominus) = -RT \ln \alpha = -RT \ln [(K_c)_2/(K_c)_1]$$

A stationary phase that produces a large degree of separation is said to have a high selectivity. The separation of two components (1 and 2) is expressed by the relative retention (α):

$$\alpha = t'_{R(2)}/t'_{R(1)} = V'_{R(2)}/V'_{R(1)} = k_{(2)}/k_{(1)} = K_{C(2)}/K_{C(1)}$$

If one of the pair is a standard substance, the symbol used for relative retention is 'r'.

Having achieved a separation it is necessary to prevent remixing of the components. The ability to achieve this is a function of the column efficiency, as measured by the plate number. The combined effects of stationary phase selectivity and column efficiency is expressed in the peak resolution (R_s) of the column. (see Figure 2):

$$R_s = \frac{(t_R)_2 - (t_R)_1}{\frac{1}{2}(w_1 + w_2)}$$

A value of $R_s = 1.5$ is normally considered to represent baseline separation for Gaussian shaped peaks. To achieve the maximum peak resolution, both high selectivity and column efficiency (giving narrow bands) are required.

Increased resolution can always be achieved by an increase in column length since the peak separation (Δt_R) is proportional to the distance of migration down the column, but peak width is only propor-

tional to the square root of the migration distance. The penalty for this, however, is longer retention times and an increased inlet pressure of mobile phase.

The Purnell equation shows how peak resolution is related to the retention factor (k), the plate number (N) and the relative retention (α):

$$R_s = \frac{\sqrt{N_2}}{4} \times \frac{(\alpha - 1)}{\alpha} \times \frac{k_2}{1 + k_2}$$

where the subscript 2 refers to the second peak.

Conditions for obtaining maximum values of the plate number have already been discussed. The relative retention is mainly governed by the nature of the stationary phase, since in GC at normal pressures, only molecular interactions between the solute molecules and the stationary phase are involved. These interactions are maximized in the concept of 'like has an affinity for like'. Thus, for a sample that contains predominantly nonpolar species a nonpolar stationary phase will optimize the dispersion forces and, since polar interactions will be absent, solutes will elute according to their volatility with the most volatile (lowest boiling point) components eluting first. For polar samples a polar stationary phase is used to maximize both dipole-dipole interactions and dipole-induced dipole interactions. Because the effect of volatility is still present, it is much more difficult to predict elution behaviour in this latter case. Most naturally occurring mixtures contain species spanning a range of polarities, and in this case it is still better to use a polar stationary phase. At least a partial separation can be achieved with α values as low as 1.05, but values in the range 1.5–3.0 are preferable and above α values ~ 5.0 little additional resolution is achieved. Peak resolution increases rapidly with increasing k values, but at values >10 the term $k_2/(1 + k_2) \rightarrow 1$ and the term plays no further part in the resolution. The use of k values <1 gives very short retention times and poor resolution, so that the optimum range for k is between 1 and 10. The retention equation $t_R = L/\bar{u}(1 + k)$ shows that retention times are a function of both the mobile phase velocity (\bar{u}) and the retention factor.

In GC, k values are controlled by temperature. The van't Hoff equation describes the change in equilibrium constant with temperature and if the phase ratio (V_s/V_M) is independent of temperature we can also write for the retention factor:

$$\frac{d \ln k}{dT} = \frac{\Delta H}{RT^2}$$

where ΔH is the enthalpy of solution (or adsorption) from the mobile phase to the stationary phase.

Figure 1 for the general elution problem also shows values of k for different zones of the chromatogram. With low k values ($k < 1$) the peaks are eluted too rapidly and there is no time for separation. With high k values ($k > 10$) elution times are long, the peaks are broad and the peaks are overresolved. This problem can be corrected using the technique of temperature programming. Assuming that this chromatogram was obtained isothermally at 100°C it would be possible to choose a lower starting temperature (say 50°C) and then raise the temperature to say 150°C over a given period of time. This would have the effect of increasing the k values for the early peaks and decreasing the k values for the later peaks, the object being to get all peaks in the optimum region $1 < k < 10$. Modern computer-controlled gas chromatographs have the facility to use isothermal periods and linear and non-linear temperature programs with multiple ramps to give better control over k values.

The retention equation also indicates that a similar effect could be achieved using the analogous technique of flow-programming and changing the carrier gas flow rate. However, increase in carrier gas flow rate gives an approximately linear effect whereas temperature programming has a logarithmic effect. In spite of this, flow programming finds a use in the separation of labile and temperature-sensitive samples where high temperatures are to be avoided.

A satisfactory separation is achieved when all three terms in the Purnell equation are optimized.

Future Developments

The theory of gas chromatography is well established and it is unlikely that there will be any significant

new developments. A greater understanding of the interactions involving new stationary phases (e.g. chiral phases), and the preparation of stationary phases with better temperature stability would lead to an extension of its application. Developments in instrumentation with new coupled techniques is also a possibility. The most likely area for further development is in the area of data handling and instrument control using the newer breed of computers.

Introduction

Today, the main columns for high performance liquid chromatography (HPLC) are of tubular design, normally manufactured from high quality stainless steel and packed with spherical ceramic particles. Termination of the columns is via a metal frit held in place by an end fitting that can accept a 1/16 in (15.9 mm) male fitting to connect the column to the HPLC instrument.

Figure 1 shows a typical conventional HPLC column. This is now a mature design that has evolved over a period of 20 years. In that time, many variations have evolved, such as cartridge columns, removable end fitting columns, radial compression columns and nonmetal columns. Today, the most common analytical column has an inner diameter (i.d.) of 4.6 mm with an outer diameter of 1/4 in (63.5 mm). However, in recent years there has been a movement to smaller i.d. columns such as 3, 2, 1 and 0.5 mm. There has also been a development of packed capillary columns having i.d. of 0.32, 0.25 and 0.1 mm. Even newer columns with i.d. 0.05 mm have been developed for capillary electrochromatography (CEC). Columns are defined in Table 1 according to their internal diameters.

The most common length of an HPLC column is 25 cm but analytical columns are available in lengths down to 3 cm and guard columns are commonly 1 cm long.

The material packed into columns is mainly silica based, spherical in shape with a particle size of 5 μm . Material of diameter 10 μm has now virtually disappeared from analytical columns and 3 μm material, although introduced in the mid-1980s, is still not widely used. Newer, smaller-diameter particles of

2 and 1 μm are also available but at the time of writing occupy a niche market only.

The Conventional Column

Conventional analytical columns are 4.6 or 4 mm i.d., 1/4 in (63.5 mm) o.d. They are manufactured from high quality stainless steel such as 316 to withstand the high pressures that are used in packing (up to 10 000 psi; 69 000 kPa) and in operating the columns (around 2500 psi; 17 000 kPa). Manufacturers take particular care with the inner bores of these tubes; some use tubing 'as-drawn', while others use electropolished tubing. There have been reports of chemical modification with silanes to the inner surface.

The column packing material is held in the column with an end frit, which in turn is held in place by the column end fitting. The frit is normally made from a sintered metal, the porosity being determined by the size of the packing material used. For 5 μm materials, a 2 μm porosity frit is normally used, but for 3 μm and smaller, a 0.5 μm frit is common. The most common type of end fittings are those manufactured by Swagelok, Parker and Valco. Typical end fittings are shown in Figure 2.

Frits are held on the column by compression fittings; although it is possible to remove the end fitting to repair or top up the packed material (or to clean or repair a damaged frit), it is not generally recommended as it is not usually possible to regain good performance. Inserting and removing these classical columns from an HPLC instrument cannot be done without tools. In an attempt to make this into a simple 'no tools operation', and to reduce the amount of hardware used in the tube section of the column, the cartridge column was developed. The first successful commercial cartridge column was designed by Brownlee Labs and is today still known as the Brownlee system.

In this system, the column design is very simple in that the tubular column has the packing material held in place by frits that are pushed into the end of the tube. This packed tube is held in the cartridge column

Figure 1 Typical HPLC column.

Table 1 Definitions of columns

Column type	Internal diameter (mm)
Analytical	20–3
Microbore	2–0.5
Capillary	< 0.5

Figure 2 Typical end fittings.

held by hand-tight end nuts that are part of and free to rotate with the cartridge holder.

Since the Brownlee system was introduced, there have been many copies on this basic design and also developments into the finger-tight removable end fitting column (Figure 3). These columns, as shown in Figure 4, again have the frit pushed into the tube or held in place by a frit cap. This frit cap also contains a seal that allows the end fitting to be screwed down onto the frit. This design has many advantages. It allows easy removal of the frit to replace it or top up the column packing material, but more importantly,

Figure 3 Finger-tight end fitting column showing frit cap.

Figure 4 Removable end fitting column.

it allows columns to be coupled together with very low dead volumes.

Apart from the cartridge and removable end fitting columns, a different design approach was taken by Waters with their radial pack systems. As mentioned previously, high pressures are used to pack particles into column to obtain a well-packed bed. In packing columns, voids in the packing bed are produced if insufficient pressures are used; these voids are commonly along the axial direction. The idea of the radial packed column is to pack the material into a soft-walled tube. This tube is held in a device that can apply radial pressure, and so reduce the radial voids. Some examples are shown in Figure 5. This radial compression system has not been applied down to small i.d. tubes, but has been developed for semipreparative systems. In preparative systems, direct axial compression on to the top of the packing is also used.

Columns down to 3 mm i.d. can be used with what is commonly classed as conventional HPLC equipment, with detector flow cells in the order of 8 μ L.

Figure 5 (See Colour Plate 21) Radial compression column cartridge.

Table 2 Volumetric flow rates required to maintain a linear flow velocity of 1.5 mm s^{-1} in columns of different diameters

Column diameter (mm)	Flow rate (mL min^{-1})	Solvent consumption (mL h^{-1})
1.0	0.04	2.4
2.0	0.18	10.8
3.0	0.39	23.4
4.0	0.7	42.0
4.6	0.93	55.8
5.0	1.1	66.0
8.0	2.81	168.6

Reducing the column diameter below 3 mm requires detectors with smaller volumes to reduce detector band broadening. Pumps that can produce lower flow rates are also required. Table 2 gives the volumetric flow rates required to maintain a linear flow velocity of 1.5 mm s^{-1} .

Although microbore columns became commercially available in the mid-1980s, they have not displaced 4.6 mm i.d. columns. Many comparison reviews were written in the 1980s of 1 mm versus 4.6 mm i.d. columns. In general the conclusion was reached that solvent saving and packing material costs did not justify the capital expenditure in new equipment and that mass sensitivity enhancements were difficult to achieve. Since then much has improved, both in the instruments and especially in the column design, particularly in the end fittings used on $< 3 \text{ mm}$ i.d. columns.

From 1990 onward, further research was conducted and there was widespread discussion of the advantages of microbore columns, including increased resolution, decreased solvent consumption, lower heat capacity, increased mass sensitivity and, most importantly, the easier coupling of these columns to secondary systems and mass spectrometers. Columns with i.d. down to 1 mm are conventionally still manufactured from stainless steel, but as the i.d. is reduced so can the wall thickness be reduced. This allows the use of other materials, as the resulting pressure forces in the small i.d. tubes is also reduced. For 2 and 1 mm columns, glass-lined tubing has been used. This is in an attempt to give a very smooth inner surface, which in turn helps column packing and hence efficiency. Columns are now available manufactured from PEEK (poly(ether ether ketone), an ICI polymer). Columns of this material are produced in diameters down to 0.5 mm.

A conventional PEEK column is shown in Figure 6, and a 0.5 mm flexible PEEK column is shown in Figure 7. These columns have no wetted metal components and, since the 0.5 mm columns are flexible,

**Figure 6** PEEK column.

for the first time in HPLC it has become possible to consider a different design of instrument, in that there is no longer any need to have a fixed distance between the injector and detector. Another feature of these columns is that they can be cut to any length. If the

**Figure 7** PEEK-o-bore column.

Figure 8 Integral guard column.

inlet blocks or becomes contaminated, then this part of the column can be cut off.

Capillary columns of less than 0.5 mm i.d. are almost exclusively manufactured from fused silica, in some cases with a metal outer case onto which the end fittings can be connected.

Guard Columns

As the name suggests, guard columns are used to protect the main analytical column. They are normally 1 cm in length, of the same diameter as the main column, and made of the same material. They are not extensively used in all application areas, possibly because they can reduce the total column efficiency and are not easy to install or replace. This is set to change with the development of removable end fitting columns. New designs, as shown in **Figure 8**, now allow easy connection and replacement of guard systems. However, manufacturers still only offer generic packings of either normal phase or reversed phase for these columns. **Figure 9** shows a guard column cartridge system that can be connected to any form of column.

Packing Materials

Porous silica is the most widely used adsorbent in HPLC, although extensive work has been conducted with alumina, zirconia and polymer supports. The majority of these supports are spherical and, for analytical applications with small molecules, have general physical parameters of pore size 10 nm, pore

Figure 9 Stand-alone guard column.

volume 0.5 mL g^{-1} and surface area $250 \text{ m}^2 \text{ g}^{-1}$. The most common particle size used in columns is $5 \mu\text{m}$. Care must be taken when using the particle size given by a manufacturer. What is meant by $5 \mu\text{m}$ particles, is actually a $5 \mu\text{m}$ particle size distribution. Depending upon the type and mode of measuring instrument used by the manufacturer, there will be a particle size distribution based on number, area or volume.

In the number distribution the percentage of the particles in each size range is determined by dividing the number in each range by the total number of particles. In the area distribution, the percentage of the surface area in each size range is determined by dividing the surface area calculated for each size range by the total surface area of all the particles. This has the effect of emphasizing the larger particles more than the number distribution. For example, one particle of $10 \mu\text{m}$ diameter has the same surface area as 100 particles of $1 \mu\text{m}$ diameter. The volume distribution is calculated from the percentage of the volume of each particle size divided by the total volume of all the sizes. The volume distribution emphasizes the large particles even more than the area distribution, e.g. a $10 \mu\text{m}$ diameter particle has the same volume as 1000 particles of $1 \mu\text{m}$. Typical distributions (for a $5 \mu\text{m}$ Spherisorb) are given in **Figure 10**, showing the emphasis on the larger particle sizes in the distributions for area and volume.

Silica particles used for packing are commonly manufactured from a sol-gel type process, starting from a cation-based sol. This produces gels that are high in their cationic species, for example Spherisorb has a sodium content of 1500 ppm. Newer manufacturing methods introduced in recent years, use organic tetraethyl orthosilicate (TEOS) condensation systems that can produce exceptionally pure silicas.

In the sol-gel process, the size of the particles can be controlled by the viscosity of the mixture, the emulsification rate and the amount and type of surfactant used to stabilize the emulsion. However, none of the processes can produce monodispersed particles – they produce a particle size distribution and the required particle size is then obtained from this by air classification or elutriation.

The tighter the particle size distribution, the more uniform a column packing can be made. However, with very tight particle size distributions it becomes more difficult to pack the columns. Van Deemter curves demonstrating the effect of particle size on the column efficiency are shown in **Figure 11**.

The surface area, pore size and pore volume of packing material are determined either by nitrogen BET or mercury porosimetry. As with particle size distributions, care must be used in the interpretation of these data because different models are used by

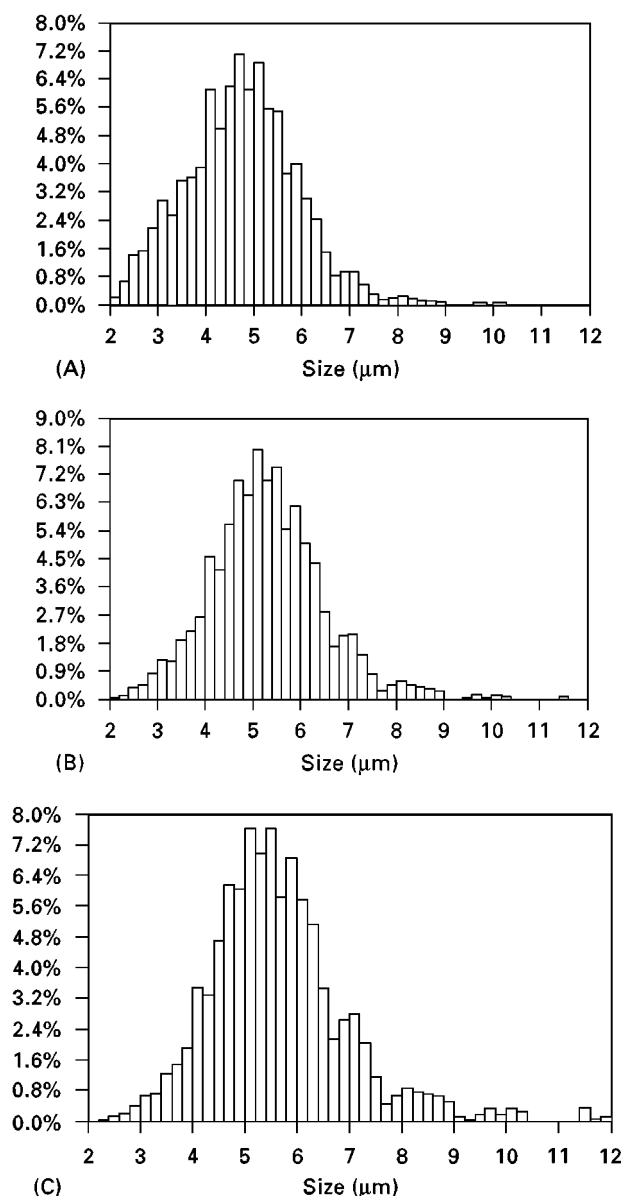

Figure 10 Particle size distributions for a 5 µm Spherisorb. (A) Number; (B) area; (C) volume.

different manufacturers, which can impose different interpretations on the type and shape of pores. In HPLC, an important factor is the absence of micropores and mesopores. Micropores are defined as having a diameter of less than 1 nm, while mesopores are less than 5 nm in diameter. If these pores are included

Figure 11 Van Deemter curves.

in the surface area calculations, then very large surface area values are obtained. However, most analyte molecules cannot penetrate into micropores and even if they could possibly penetrate into the mesopores, diffusion is very restricted by steric hindrance, which in turn affects mass transfer and hence efficiency.

Silica is a preferred adsorbent in HPLC as the surface characteristics can be modified by chemical reaction to change the hydrophilic silica surface into a hydrophobic surface suitable for reversed-phase chromatography, or to place an ionic exchange material on the surface for ion exchange chromatography.

A very broad range of functionality can be attached to the silica surface, through reaction with organosilanes, the most popular being C₁₈ or octadecylsilane. The linkage onto the silica is of the type Si-O-Si-R, where R is the functional group. Manufacturers use a variety of silanes, ranging from monochloro to trichlorosilanes to mono and tri methoxy and ethoxy silanes. Attachment of the monofunctional silane onto the surface of the silica leads to a monomeric phase, while the addition of small amounts of water into the bonding process can lead to polymeric phases.

Manufacturers normally give bonding figures as % carbon loadings. This is a very misleading figure as the percentage of carbon loading alone is not a relevant parameter because of differences in the surface area of the original silica, which result in different surface densities of the bonded alkyl groups. **Table 3**

Table 3 Column packing parameters

Description	Column volume (mL)	Si density (g mL ⁻¹)	Mass of packing (g)	Carbon load (%)	Amount of carbon in the column (g)
Nova-Pak C ₁₈	1.8	0.91	1.64	7	0.12
µBondapak C ₁₈	1.8	0.46	0.82	10	0.08

Table 4 Some commercially available bonded phases

<i>Phase name</i>	<i>Usage</i>	<i>Comments</i>
C ₁	Purification	
C ₄	Protein separations	
C ₆	Protein separations	
C ₈	General purpose	Almost 80% of all applications have been developed with C ₈ and C ₁₈ phases
C ₁₈ ODS	General purpose	Almost 80% of all applications have been developed with C ₈ and C ₁₈ phases
Phenyl	Separation of complex mixtures	Induced dipole interactions with polar analytes
Cyano CN	Broad spectrum of mixtures with different polarities	Can be used in both normal and reversed phase
Amino NH ₂	Sugar analysis and for aromatic compounds	Weak anion exchanger
Diol	Complex mixtures	Slightly polar adsorbent for normal phase
Ion exchange	Ionic species	
Chiral phases	Enantiomer separations	Four major types available: donor, polymer, cavity and exchange

ODS, octadecylsilica.

outlines this problem, showing the amount of carbon on a material against its percentage carbon loading.

Table 4 provides a broad summary of the bonded phases that are commercially available. It must be stressed that this is in no way an extensive list. There are many specialized phase-column combinations supplied by many manufacturers. In particular, these specialized phases tend to be in the chiral separation areas.

The term end-capping was introduced in the late 1970s to indicate that a secondary treatment had been applied to a bonded phase. This was an attempt to cover all available silanols. The most common end-capping agent is trimethylchlorosilane; this molecule is relatively small and so can penetrate into the pore system of the adsorbent. Generally end-capping leads to an improvement in the chromatography of basic compounds. However, even after the best end-capping, it is estimated that about 50% of all silanols are still unbonded.

A term that has recently been introduced into column packings is 'base-deactivated' reversed phases. This is a particularly unfortunate term since these packings are not deactivated with bases but have surface treatments or treatments of the silica that make them particularly useful for separating basic compounds. Amines, for example, tend to tail on conventional reversed-phase column packings because of the residual acidic silanols. These base-deactivated packings are normally manufactured from the new pure silicas and have a more uniform or reduced level of silanols.

A major problem with silica is the small pH range over which the adsorbent can be used. Above pH 8.5 the siloxane bridge is broken, leading to breakdown through solvation of the particle. Below pH 2.5, the bonded phase is hydrolysed from the surface of the silica. In an attempt to extend the pH range of silica, attempts have been made to manufacture pH-stable

bondings. These have normally been based on coating the silica with a polymer, such as polybutadiene or a grafted polysiloxane.

Other ceramics have been reported as packing materials. The most common are alumina, zirconia and titania. Although it is possible to attach hydrophobic groups onto all of these materials, with alumina the silane is very easily removed from the surface. To obtain a hydrophobic character for alumina, polybutadiene or grafted polysiloxane polymers are used. These types of bondings have been divided into two groups. The first comprises those polymers with siloxane bonds such as polymethyloctylsiloxane, polymethyloctadecylsiloxane and silica monomers, while the second is represented by purely organic monomers and oligomers such as polybutadiene.

Another support that has been developed and can be used under very aggressive conditions is porous graphitic carbon.

Polymer-based adsorbents are also used as a support material in HPLC columns. They are manufactured from synthetic cross-linked organic polymers. Their main application area is in size-exclusion chromatography and ion exchange chromatography. In normal-phase and reversed-phase HPLC they still have very few applications. A problem is that even though the new polymer packings are highly cross-linked and stable, they still carry the history of their precursors and they can swell with some solvents.

Conclusions

Much has changed over the last few years in both the manufacture of support materials and the design of columns. Manufacturers of supports now make more reproducible materials and very pure forms of support materials, especially in silica, where metal

impurity levels are now less than 5 ppm (the first silicas used had typical impurity levels of 1000–2000 ppm). In the silica support materials the latest developments have been towards base-deactivated materials and have tended to focus on the new very pure silicas. Particle size distributions have also become tighter around given means, leading to more stable and reproducible columns.

In column design, the move has been to cartridge type systems having smaller tube i.d. with smaller particles and shorter lengths.

The focus on development is now moving to micro systems. Future developments are likely to be systems with smaller and smaller column i.d., and even complete columns on microchips.

Introduction

Countercurrent chromatography (CCC) belongs to the family of liquid partition chromatography but with one distinct feature: the system totally eliminates the use of a solid support. Unlike liquid chromatography (LC), CCC utilizes two immiscible solvent phases. The partition process takes place in an open column where one phase (the mobile phase) continuously passes through the other (stationary phase), which is permanently retained in the column. To retain the stationary phase within the column, the system uses effective combinations of the column configuration and a force field (gravitational or centrifugal). Hence CCC instruments display a variety of forms that are quite different from those used in LC.

Because no solid support is used, CCC can eliminate all the complications arising from the use of a solid support such as adsorptive sample loss and denaturation, tailing of solute peaks and contamination.

The Two Basic CCC Systems

All existing CCC systems have been developed from two basic forms, the hydrostatic equilibrium system and the hydrodynamic equilibrium system (Figure 1).

The basic hydrostatic system (left) uses a stationary coiled tube. The coil is first filled with the stationary phase (either the lighter or the heavier phase of an equilibrated two-phase solvent system) and the mobile phase is introduced from one end of the coil. Owing to the action of gravity, the mobile phase percolates through the segment of the stationary phase in one side of the coil. This process continues until the mobile phase reaches the other end of the coil. Thereafter the mobile phase only displaces the same phase leaving the stationary phase in the coil. Consequently, solutes introduced at the inlet of the coil are partitioned between the two phases in each helical turn and separated according to their partition coefficients.

The basic hydrodynamic system (right) uses a similar arrangement except that the coil is rotated around its own axis. This simple motion produces a profound effect on the hydrodynamic process in the coil by generating an Archimedean screw force. All

Figure 1 Two basic CCC systems. (A) Hydrostatic equilibrium system. (B) Hydrodynamic equilibrium system.

materials present in the coil that are either heavier or lighter than the suspending medium are driven toward one end of the coil. This end is conventionally called the head; the other end is called the tail.

Owing to the effect of this Archimedean screw force, the mobile phase introduced through the head end of the coil immediately interacts with the stationary phase to establish a hydrodynamic equilibrium. The two solvent phases are distributed fairly evenly in each helical turn where they are vigorously mixed by the rotation of the coil. After the entire coil reaches this equilibrium state, the mobile phase only displaces the same phase, leaving a large amount of the other phase stationary in the coil. Consequently, solutes introduced through the inlet of the coil are efficiently separated and eluted out in the order of their partition coefficients.

Each basic CCC system described above has its own merits. The hydrostatic system gives a stable retention of the stationary phase whereas the hydrodynamic system yields a higher partition efficiency by vigorous mixing of the two phases with the rotation of the coil. Several efficient CCC systems have been developed from each basic system.

Hydrostatic CCC Systems

During the early 1970s, hydrostatic CCC systems were rapidly developed because of their simplicity. Typical hydrostatic CCC systems are schematically illustrated in Figure 2. They are classified into gravitational and centrifugal schemes.

In the gravitational schemes, the basic hydrostatic equilibrium systems (HSES, shown in Figures 1 and 2, left) is modified as follows. One side of the coil,

which is entirely occupied by the mobile phase and therefore forms an inefficient dead space, is displaced with narrow bore transfer tubes, while the other side of the coil, which provides an efficient column space, is changed to large-bore straight tubes. In droplet CCC (DCCC, Figure 2A), the vertical column is first filled with the stationary phase and the mobile phase is introduced from one end. The mobile phase then forms multiple droplets, each occupying the space across the diameter of the column, thus dividing the column into a number of partition units. The system requires use of a proper solvent system for droplet

Figure 2 Development of hydrostatic CCC systems. These diagrams illustrate a variety of CCC schemes developed from the basic hydrostatic equilibrium system (HSES) shown in Figure 1, left. They are divided into the gravitational (upper) and centrifugal (lower) schemes.

formation. Rotation locular CCC (RLCCC, Figure 2B) utilizes a locular column prepared by the insertion of centrally perforated discs to divide the column space into multiple partition units called locules. This locular column is first filled with the stationary phase followed by introduction of the mobile phase at one end while the column is tilted and rotated about its own axis. When both column inclination and rotation speed are optimized, each locule holds a desired volume of the stationary phase, which is steadily mixed with the mobile phase by the rotation of the column.

In the centrifugal schemes, analytical helix CCC (HCCC) was developed by reducing the dimensions of the coil, which is then placed around the periphery of a centrifuge bowl (Figure 2C). Under a centrifugal force field the same partition process takes place in

each turn of the coil as observed in the basic hydrostatic system, but with a much higher efficiency due to the reduced column dimensions. Another centrifugal scheme called centrifugal droplet CCC (CDCCC) performs droplet CCC in a centrifugal force field (Figure 2D).

Hydrodynamic CCC Systems

Rotary-Seal-Free-Flow-Through Systems

The development of the hydrodynamic CCC systems was initiated by introduction of various flow-through centrifuge systems that can perform continuous elution without the use of conventional rotary seals. A series of such centrifuge systems is schematically illustrated in Figure 3. The diagrams show the

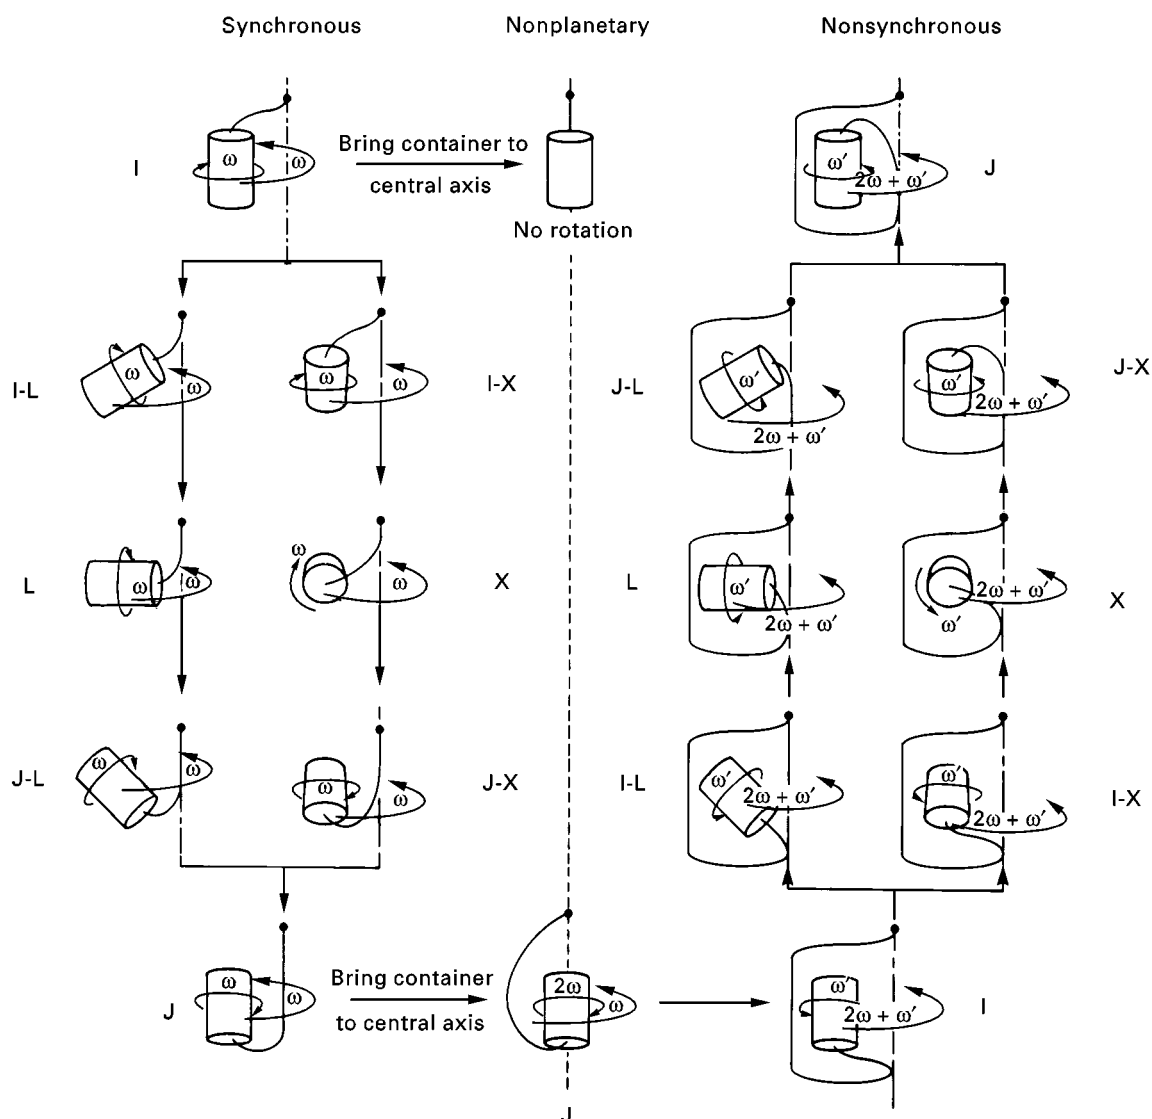

Figure 3 A series of flow-through centrifuge systems free of rotary seals.

orientation and motion of a cylindrical coil holder with a bundle of flow tubes, the end of which is supported on the centrifuge axis at the point marked with a black dot.

These centrifuge systems are classified in three groups according to their modes of planetary motion. The synchronous schemes (left column) produce a synchronous planetary motion of the coil holder, i.e. one rotation about its own axis during one revolution around the central axis of the centrifuge. In the nonsynchronous schemes (right column) the rates of rotation and revolution of the holder are independently adjustable. The nonplanetary scheme (middle column) produces simple rotation as in the conventional centrifuge system. In the Type I synchronous planetary motion (left, top) the holder revolves around the central axis of the centrifuge and synchronously rotates about its own axis in the opposite direction. This synchronous counterrotation of the holder steadily unwinds the twist of the tube bundle caused by revolution, thus eliminating the need for the rotary seal. This same principle can be applied to other synchronous schemes with tilted (Types I-L and I-X), horizontal (Types L and X), dipping (Types J-L and J-X) or even inverted (Type J) orientation of the holder. The Type J synchronous scheme is a transitional form to the nonplanetary scheme. When the holder of the Type J synchronous scheme is shifted to the central axis of the centrifuge, the rates of rotation (ω) and revolution (ω) of the holder are added and the holder rotates at an angular velocity of 2ω . In this case the tube bundle rotates around the holder at ω in the same direction as that of the holder to unwind the twist caused by the rotation of the holder. This nonplanetary scheme is further transformed to the nonsynchronous schemes. On the base of the nonplanetary scheme, the holder is again shifted towards the periphery of the centrifuge to perform a synchronous planetary motion. By selecting the holder orientation as specified in the synchronous schemes, the respective types of nonsynchronous schemes are produced.

Each scheme produces a specific pattern of the centrifugal force field that can be utilized for performing CCC. Among these, the Type J synchronous planetary motion is found to be most useful since it can perform high speed CCC that yields efficient separations in a short elution time.

Mechanism of High Speed CCC

The design of the Type J coil planet centrifuge is schematically illustrated in Figure 4. A cylindrical coil holder is equipped with a gear that is coupled to an identical stationary gear mounted at the central

Figure 4 Design principle of Type J coil planet centrifuge.

axis of the centrifuge. This gear arrangement produces a synchronous planetary motion of the coil holder, i.e. revolution around the central axis of the centrifuge and rotation about its own axis, both at the same angular velocity and in the same direction as indicated by the arrows. As mentioned earlier, this planetary motion prevents the flow tubes from twisting and, therefore, the system permits continuous elution through the rotating column without the use of a conventional rotary seal device. The coil is directly wound around the holder as shown in the diagram. In practice, a long tube (usually over 100 m in length) is wound around a spool-shaped holder to form multiple coiled layers.

The mechanism of high speed CCC using this centrifuge design is illustrated in Figure 5, where all coils are shown as straight tubes for simplicity. When the coil is filled with two immiscible solvent phases and subjected to the planetary motion, the two phases are distributed in the coil in such a way that one phase (head phase) entirely occupies the head side and the other phase (tail phase) occupies the tail side (Figure 5A). This unilateral hydrodynamic distribution of

Figure 5 Mechanism of high-speed CCC. (A) Bilateral hydrodynamic equilibrium in a closed coil. (B) One-way elution modes. (C) Dual countercurrent system.

the two phases clearly indicates that the head phase (white), if introduced at the tail, would travel through the tail phase (black) toward the head, and similarly the tail phase, if introduced at the head, would travel through the head phase toward the tail. The above hydrodynamic trend can be efficiently utilized for performing CCC in two elution modes as shown in Figure 5B. The coil is first filled with the head phase (white) followed by elution with the tail phase (black) from the head toward the tail of the coil. Alternatively, the coil is filled with the tail phase followed by elution of the head phase from the tail toward the head of the coil. In either case, the mobile phase quickly flows through the coil and is collected from the other end, leaving a large volume of the stationary phase in the coil. Consequently, solutes locally introduced at the inlet of the coil are separated in a short period of time.

The system also permits simultaneous introduction of the two solvent phases through the respective terminals of the coil to induce a true countercurrent flow of the two phases. This dual CCC system requires an additional flow tube at each end of the coil to collect the effluent and, if desired, a sample injection tube at the middle portion of the coil as shown in Figure 5C. In addition to the liquid-liquid dual CCC, this system provides a unique application to foam separation. In the foam CCC system, gas and liquid phases undergo a true countercurrent flow through a long narrow coiled tube with the aid of the Type J synchronous planetary motion. When the liquid phase contains a surfactant, the above countercurrent process produces a foaming stream that moves with the gas phase toward the tail. The sample mixture introduced at the middle of the column is separated into its components according to their foam affinity; foam active components are quickly carried with the foaming stream toward the tail whereas the remainder is carried in the liquid stream in the opposite direction and collected at the head end of the coil. For samples with a strong foaming capacity such as proteins and peptides (bactracin), foam CCC can be performed without the use of the surfactant in the liquid phase.

In addition to the Type J planetary motion described above, some other synchronous planetary motions can produce the unilateral phase distribution (Figure 5A) that can be utilized for performing high speed CCC. Among these, the hybrid systems between Types X and L (see Figure 3) are extremely useful because they can retain a satisfactory volume of the stationary phase for viscous polymer phase systems that are used for partition of macromolecules and cell particles.

The hydrodynamic motion of the two solvent phases in the Type J high speed CCC system has been

observed under stroboscopic illumination. A spiral column was filled with the stationary phase and the coloured mobile phase was eluted through the column in a suitable elution mode. After the steady-state hydrodynamic equilibrium was reached, the spiral column showed two distinct zones. As shown in the upper diagram in Figure 6, vigorous mixing of the two solvent phases was observed in about one quarter of the column area near the centre of the centrifuge (mixing zone), while two phases are clearly separated into two layers in the rest of the area (settling zone). Because the location of the mixing zone is fixed with respect to the centrifuge system, while the spiral column rotates about its own axis, each mixing zone is travelling through the liquid like a wave of water over the sea, as shown in the bottom diagram in Figure 6. This highlights an important fact: at any given portion of the column the two solvent phases are subjected to a repetitive partition process of alternating mixing and settling at a high frequency of over 13 times per second at 800 rpm of column rotation.

This explains the high partition efficiency attained by high speed CCC. Figure 7 shows a typical separation of flavonoids from sea buckthorn (*Hippophae rhamnoides*) produced by the standard high speed CCC technique. Major components including isorhamnetin and quercetin are well resolved within 3 h at partition efficiencies ranging from 2000 to 3000 theoretical plates.

Standard Procedure of CCC

Selection of Two-Phase Solvent System

The first and most important step in CCC is to choose a proper solvent system that can satisfy the following requirements: the sample should be soluble and stable in the solvent system; the solvent system should provide a suitable partition coefficient for the target compounds; and it should produce a satisfactory retention of the stationary phase in the column. The partition coefficient and retention of the stationary phase are discussed below.

Partition coefficient CCC differs from other types of chromatography in that it uses two solvent phases and, therefore, the partition coefficient of the solute can be easily determined by a test tube experiment prior to the separation. In each measurement the sample is first partitioned between equilibrated two-solvent phases in a test tube, an aliquot of each phase is removed, and then the concentration of the solute in each aliquot is measured by ultraviolet or visual wavelength absorbance. Other methods of measurement such as radioactivity, enzymatic activity, etc., can be used. The partition coefficient, K , is the ratio between these two measurements and expressed in various ways such as $K(U/L) = C_U/C_L$ (solute concentration in the upper phase divided by that in the lower

phase), $K(S/M) = C_S/C_M$ (solute concentration in the stationary phase divided by that in the mobile phase), etc. When the sample is a mixture of multiple components, the partition coefficient of each component can be obtained by high performance liquid chromatography (HPLC), gas chromatography (GC) or thin-layer chromatography (TLC) analysis of each phase and by comparing the peak height or area of the corresponding peaks in the two chromatograms. In general the most suitable range of K value is $1 < K(S/M) < 2$ for the hydrostatic CCC systems and $0.5 < K(S/M) < 1$ for the hydrodynamic CCC systems. Once the K value has been determined, the retention volume of the solute can be computed from the following equation:

$$V_R = V_{SF} + K(S/M)(V_C - V_{SF})$$

where V_R is the retention volume of the solute, V_{SF} the retention volume of the solvent front (amount of the mobile phase in the column), and V_C the total column capacity.

Retention of stationary phase The retention of the stationary phase in the separation column is an important factor in determining the resolution of solute peaks in CCC. Generally, the greater the retention of the stationary phase, the better the separation. In hydrostatic systems, in which the phase mixing is not violent, the retention of the stationary phase is conveniently adjusted by varying the flow rate of the mobile phase and/or the rotation speed in the centrifugal CCC system. In hydrodynamic systems, which provide efficient mixing of the two phases, stationary phase retention requires more careful selection of the two-solvent system as well as the choice of the mobile phase and its elution mode. In high speed CCC using the Type J planetary motion, the settling time of the two solvent phases under gravity provides a useful measure for the stationary phase retention and the elution mode. The test is performed as follows: the two phases are preequilibrated in a separatory funnel and 2 mL of each phase is delivered into a 5 mL capacity graduated cylinder equipped with a stopper (an ordinary glass test tube, 13 mm o.d. and 10 cm long with a polyethylene cap can also be used). The contents are gently mixed by inverting the container five times and the time required to form two clear layers is measured. If this settling time is within 30 s, the solvent system can be used for separation by eluting the lower phase from the head toward the tail or the upper phase in the reversed mode. If the settling time exceeds 30 s, the above elution mode should be reversed while the retention of the stationary phase is usually considerably lower than an optimum range. However, this settling time test is not

applied to the cross-axis coil planet centrifuge systems based on the planetary motions of Type X, Type L and their hybrid systems (see Figure 3, left column). These centrifuge systems provide excellent retention of the stationary phase for almost all two-phase solvent systems including viscous polymer phase systems used for partition of macromolecules and cell particles.

The retention of the stationary phase in the hydrodynamic CCC systems has been extensively studied using various two-phase solvent systems. These results are summarized in a set of phase distribution diagrams that will provide a valuable guide for users of high speed CCC systems (see Further Reading).

Preparation of the Sample Solution

In CCC, the sample solution is usually prepared by dissolving the sample in the solvents used for the separation. If the amount of sample is small, it may be dissolved in the stationary phase. However, if the sample mixture contains multiple components with a wide range of polarity, it should be dissolved in both solvent phases. In this way, the volume of the sample solution is minimized and also the two-phase formation in the sample solution is ensured. Occasionally, a single phase is formed after dissolving a large amount of the sample, which would result in a detrimental loss of the stationary phase from the column. If this occurs, the sample solution should be diluted with the solvent until two phases are formed. Although CCC permits the loading of the sample solution containing undissolved particulates, the best results are obtained by filtering the sample solution before introduction into the column.

As in other forms of LC, the amount of sample and sample solution affects the separation. Usually, a typical semipreparative column with about 300 mL capacity will separate up to a few hundred milligrams of sample dissolved in 10 mL of the solvent mixture without significantly affecting the partition efficiency.

Elution Procedure

In both hydrostatic and hydrodynamic CCC, separation is initiated by filling the entire column with the stationary phase of a mutually equilibrated two-phase solvent system. This is followed by injection of the sample solution through the sample port. Then, the mobile phase is eluted through the column in the correct elution mode while the apparatus is rotated at a suitable speed (except for DCCC). Although sample injection may be made after the column had been equilibrated with the mobile phase (the routine procedure in HPLC), this practice does not usually improve the separation in CCC.

In hydrostatic CCC systems, the direction of eluting the mobile phase should be chosen in such a way that the upper phase is eluted against the acting force field (ascending mode), and the lower phase along the force field (descending mode). In hydrodynamic CCC systems, the direction of the Archimedean screw force also plays an important role in the retention of the stationary phase. Generally speaking, the lower phase should be eluted from the head toward the tail, and vice versa for the upper phase. For various polymer phase systems (such as polyethylene glycol/dextran) with a high viscosity, maximum retention of the stationary phase is usually obtained by using the less viscous phase as the mobile phase.

As in HPLC, CCC permits the use of gradient or stepwise elution. The method requires suitable selection of the solvent system so that the volume of the stationary phase in the column is not significantly altered by the mobile phase. Some examples are *n*-butanol/water with a concentration gradient of dichloroacetic acid or trifluoroacetic acid, and polymer phase systems with a pH gradient of sodium or potassium phosphate.

Detection

In the past, detection of the CCC effluent has been performed by adapting the UV/visible absorbance monitoring system used in HPLC. In this case, a straight vertical flow cell should be used. In order to avoid trapping the droplets of the stationary phase in the cell, the mobile lower phase should be introduced from the bottom of the flow cell upward and the mobile upper phase from the top of the flow cell downward. In addition to absorbance measurement, other monitoring methods may also be used which include post-column reaction, interfacing with a mass spectrometer or nuclear magnetic resonance (NMR), laser light scattering detection, pH or conductivity measurement, etc. Most of these methods are less sensitive to the carryover of the stationary phase droplets and therefore will produce better elution curves.

Variations of Countercurrent Chromatography

The standard CCC technique described above may be modified so that it is suitable for a particular type of separation. Many of these modified CCC schemes have their counterpart in LC, utilizing a solid support matrix. Table 1 summarizes the relationship between a variety of CCC techniques and their counterparts in LC.

Table 1 Variations of CCC with their counterparts in LC with solid support matrix

CCC	Description	Counterpart in LC
Normal mode	Organic phase mobile	Normal-phase LC
Reversed mode	Aqueous phase mobile	Reversed-phase LC
Dual mode	Both phases mobile	Moving-bed LC
Ion CCC	Ion exchanger in SP ^a	Ion LC
Affinity CCC	Affinity ligand in SP	Affinity LC
pH-Zone-refining CCC	Retainer in SP; eluter in MP ^b	Displacement LC
Chiral CCC	Chiral selector in SP	Chiral LC

^aSP, stationary phase.^bMP, mobile phase.

Ion CCC

Analogous to ion chromatography, CCC can separate both inorganic and organic ions according to their pK_a of affinity to the ionic ligand dissolved in the stationary phase. One example is illustrated in Figure 8, which shows separation of rare earth elements by pH gradient elution of a hydrochloric acid mobile phase through a hexane stationary phase containing a ligand, di-(2-ethylhexyl)phosphoric acid. Figure 9 is another example showing the separation of catecholamine. The left chromatogram, obtained with a ligand-free solvent system, shows no sign of separation (Figure 9A). When a basic ligand, triethylamine, is added to the stationary phase, all components are resolved (Figure 9B).

Chiral Countercurrent Chromatography

Enantiomers may be resolved by CCC if an appropriate chiral selector is present in the stationary phase. Figure 10 shows the separation of four enantiomeric

Figure 8 Analysis of rare earth elements by pH gradient elution with a ligand in the stationary phase. Apparatus, HS CCC centrifuge with 7.5 cm revolution radius; column, three multilayer coils, 1.1 mm i.d. \times 300 m, 270 mL capacity; stationary phase, 0.003 mol L⁻¹ di-(2-ethylhexyl)phosphoric acid in *n*-heptane; mobile phase, exponential gradient of 0–0.4 mol L⁻¹ HCl; sample, 0.001 mol L⁻¹ each of La, Ce, Pr, Nd, Sm, Eu, Gd, Tb, Dy, Ho, Er, Tm, Yb and Lu in 100 μ L; revolution, 900 rev min⁻¹; flow rate, 5 mL min⁻¹; pressure, 300 psi (\sim 2070 kPa).

pairs of dinitrobenzoyl amino acids using a chiral selector, *N*-dodecanoyl-L-proline-3,5-dimethylanilide in the stationary phase. When the separation is performed without the chiral selector, all components elute near the solvent front, resulting in poor separation (Figure 10A). The addition of the chiral selector to the stationary phase results in excellent separation with only one overlapping peak under otherwise identical experimental conditions (Figure 10B). Gram quantities of ionic enantiomers can be purified by means of the pH-zone-refining CCC technique described below.

Figure 9 Separation of catecholamine and related compounds by high speed CCC using a ligand, triethylamine, in the stationary phase. The left chromatogram (A) obtained without ligand shows no evidence of separation. All components were completely resolved by introducing the ligand in the stationary phase, as shown in part (B).

Figure 10 Separation of four enantiomeric dinitrobenzoyl (DNB) amino acids by high speed CCC, with (B), and without (A), a chiral selector, *N*-dodecanoyl-L-proline-3,5-dimethylanilide (DPA). In the upper chromatogram obtained without chiral selector, all components eluted near the solvent front with poor peak resolution. Introduction of 1.6 g of DPA in the stationary phase under otherwise identical experimental conditions resulted in a remarkable improvement in peak resolution.

pH-Zone-Refining CCC

This preparative CCC technique produces a train of highly concentrated rectangular peaks similar to those obtained in displacement chromatography. The method utilizes a retainer acid or base in the stationary phase and an eluter counterion in the mobile

phase. Interaction of ionic analytes forms a series of solute zones with sharp boundaries that move together through the column at the same rate (isotachic movement). Each zone consists of a single species, has its own specific pH and is arranged in the order of its pK_a and hydrophobicity. Charged minor components are concentrated at the boundaries of the major zone

Figure 11 Separation of eight (Z)-(benzyloxycarbonyl) dipeptides by pH-zone-refining CCC.

Figure 12 Separation of (±)-dinitrobenzoyl leucine ((±) DNB-leu) by pH-zone-refining CCC.

and are eluted as sharp peaks. **Figure 11** shows the separation of eight (Z)-(benzyl-oxycarbonyl) dipeptides by pH-zone-refining CCC. All components (100 mg of each) are well resolved with minimum mixing zones as evidenced by the sharp transitions of their partition coefficients (K_{std}) measured with a standard two-phase solvent system.

The method can also be applied to preparative-scale chiral separation using a chiral selector in the stationary phase. **Figure 12** illustrates separation of

2 g of (±)-dinitrobenzoyl leucine by pH-zone-refining CCC. pH-zone-refining CCC is described in detail in texts listed in Further Reading.

CCC with Polymer Phase Systems

Separation of proteins requires the use of aqueous–aqueous polymer phase systems to prevent denaturation of the analytes by organic solvents. **Figure 13** shows separation of four stable proteins by a polymer phase system composed of 12.5% (w/w) polyethylene glycol 1000 and 12.5% (w/w) dibasic potassium phosphate. The separation was performed by a cross-axis coil planet centrifuge (hybrid between Type L and X in Figure 2). The method has also been successfully applied for purification of recombinant enzymes.

Conclusions

Countercurrent chromatography covers a broad spectrum of samples ranging from small ions to macromolecules. The method provides various advantages over conventional liquid chromatographic techniques such as no sample loss and denaturation due to the solid support, high purity of fractions and high reproducibility. The CCC technique is particularly suitable for preparative separations of natural and synthetic compounds.

Derivatization

Copyright © 2000 Academic Press

Introduction

Derivatization involves changing in some way the basic chemical or physical structure of a compound, usually to a single product, which may be more useful for the analysis of the original analyte in liquid chromatography (LC). Derivatization can be used for analytical or preparative scale LC. In the analytical mode, it can be used to improve the identification and quantitation of the analyte of interest. It may also be used to improve throughput and recovery in preparative scale LC purifications of large amounts of material. Changes in the basic structure of the analyte can also lead to improved peak shape, elution times, peak symmetry, efficiency, plate count, and other indicators of chromatographic performance. That is, elution times and retention factors, as well as resolution, separation factors, reduced plate heights, and other LC parameters of performance, can all be varied and improved by suitable, selective derivatization of the starting analyte.

The most general type of derivatization involves modifying the chemical structure of the starting compound by tagging or adding another reagent to it via a suitable functional group alteration (Figure 1). Thus, most simple derivatizations involve a derivatiz-

ing reagent, the substrate or analyte of interest, the desired derivative of the analyte, remaining excess reagent, and undesirable by-products coming from the excess derivatizing reagent reacting with solvent, water or thermally degrading (Figure 1). Ideally, only the desired derivative would remain at the end of the reaction period, without any remaining starting analyte, derivatizing reagent or by-products. However, this idealized situation is rarely observed and it is often necessary to separate prior to or during the LC analysis the desired derivative from all other possible compounds coming from the derivatization reaction and/or sample components and their possible derivatization products.

Though most derivatizations usually occur in a homogeneous solution between the analyte of interest and the reagent itself, it is possible to perform derivatizations on the analyte in solution with an immobilized or solid-phase reagent. Figure 2 illustrates a typical immobilized or solid-phase reagent that has been described in the literature for use with LC. It is also feasible to first immobilize the analyte on a solid support, such as silica gel, Immobilon™ membrane, poly(styrene-divinylbenzene), C₁₈ packing material, and others, and then perform the derivatization reaction on the now-immobilized analyte. Once the reaction is completed, the excess reagent is simply washed from the solid support still containing the derivative. The desired derivative is then eluted with a stronger solvent from the solid support, often in a disposable plastic tube (solid-phase extraction cartridge or Sep-Pak™), without any residual, unreacted starting

Figure 1 Chemical derivatization of an analyte using 6-aminoquinoyl-*N*-hydroxysuccinimide carbamate (6-AQC) reagent. This is a homogeneous reaction that occurs in solution. The 6-AQC degrades with water to form 6-aminoquinoline and *N*-hydroxysuccinimide, with the release of carbon dioxide.

analyte or by-products of the reagent, in a state suitable for direct LC injection.

Other approaches to derivatization involve the use of photochemical reactions, usually performed on-line after the separation occurs, which convert the starting analyte into one or more derivatives with improved detection properties (ultraviolet (UV), fluorescent (FL), electrochemical (EC), etc). This does not introduce excess derivatizing reagent, reagent by-products or hydrolysis products, since the reagent itself is light rather than a chemical. Such approaches have become popular in LC applications. It is also possible to utilize electrochemistry to perform de-

derivatizations in LC, as well as microwave digestion, immobilized enzyme reactors, pH alteration of the mobile phase after the separation, etc. **Table 1** summarizes the most commonly utilized derivatization techniques described in LC other than simple, chemical reactions.

General Approaches to Derivatization in Liquid Chromatography

Chemical derivatization in LC requires the optimization of several reaction or separation parameters. These include temperature, pH, solvent, time, ratio of

Figure 2 Typical immobilized or solid-phase reagent. The 6-AQ-tagged polymeric reagent reacts with amines (70°C, 10 min), producing a derivative free in solution, now 6-AQ derived. (6-AQ, 6-aminoquinoline; PSt, polystyrene.)

Table 1 Summary of common derivatization approaches, other than chemical reactions, used in LC

1. Photochemical conversions, photohydrolysis reactions, photocleavage or photoextrusion reactions, photobleaching, etc.
2. Electrochemical conversions (amperometric or coulometric), oxidative or reductive reactions to convert an electrochemically inactive analyte into an electrochemically active derivative.
3. Enzymatic conversions, enzyme–substrate reaction detection, used to detect enzymes post-column via their reaction with substrate and formation of the conversion product, which may then be UV, FL, EC and/or MS active. This is detection of enzymes first separated by LC.
4. Microwave digestion reactions, post-column, used to digest proteins/peptides, nucleic acids and other biopolymers, leading to monomeric species that are more easily detected (EC) and/or derivatized before final detection (e.g. proteins → amino acids + OPA → tagged amino acids; UV, FL, or EC active).
5. Immunodetection (ID), post-column in LC, used to tag an antigenic species with a FL or enzyme-tagged antibody, leading to indirect detection of the untagged antigen via its complex formation in a sandwich format. A primary antibody must be immobilized on the solid ID support to initially capture the antigen after separation by LC.
6. Enzymatic conversion of a substrate, post-column, to form the turnover product with improved UV, FL or EC detection properties. This is detection of enzyme substrates, first separated by LC, then detected post-column by addition of enzyme in solution or via an immobilized enzyme reactor column, pre-detection.

reagent to substrate, separation of derivative from sample components and reaction by-products, detector optimization for derivatives, chromatographic optimization of derivative peak shape, generation of standard derivative and structure confirmation, production of derivative calibration plot for quantitation, etc. The purity of the derivative peak in a sample must also be demonstrated by online photodiode array (PDA) or mass spectrometric (MS) methods. The derivatization reagent must be well characterized with regard to structure and its purity demonstrated. The reaction conditions need to be optimized to minimize reagent consumption, maximize derivative yield, and eliminate the formation or presence of reaction and reagent by-products that might interfere in the final separation and detection steps. It may even be necessary or desirable initially (pre-LC) to separate the excess reagent from the derivative and then introduce just the sample and the now-formed derivative into the analytical LC column.

Sometimes the reagents used have different detector properties from the final derivatives. The excess reagent at the end of the derivatization reaction

may then be transparent under the optimized detection conditions for the derivative. It may even coelute together with the derivative peak, yet not be observed under such detection conditions. This reduces the need for initial separation of excess, unreacted reagent from the derivative and sample, and/or optimization of LC conditions so that the derivative peak appears completely resolved from all the other peaks.

Large versus Small Analyte Molecules and Their Derivatizations

It is generally easier to derivatize small molecules than large ones, since the rates of chemical reactions of very large biomolecules are usually orders of magnitude slower than those of smaller species. This is a function of effective chemical collisions, the number of chemical collisions per unit time between reactive sites, conformational preferences of large biomolecules, and the number of active sites available in a biomolecule. That is not to say that biomolecules cannot be successfully derivatized – they often are and can be – but the efficiency of derivatization (percent derivatization per unit time) versus smaller reactive species is usually much less. Also, the energy of activation needed to derivatize a primary amino group in a large molecule is often much larger than that for a very small molecule having the same functionality. This is, of course, a function of the neighbouring groups, conformational preferences, conformations available, hydrogen bonding within the biomolecule, and other factors. A considerable danger with derivatizing large molecules (typically biopolymers) stems from the fact that, in most cases, such a polymer possesses a number of reactive groups, for reasons just specified, which may differ in their reactivity. The result may be the formation of a number of products bearing the same tag in different mole per mole ratios. Although in enzymatic amplification techniques the formation of multiple products helps identification, in the situation just described the formation of multiple derivatization products should be avoided. The separation of such mixtures is often difficult, usually resulting in broad peaks and low plate counts. Moreover, it may be difficult to trace back which derivative was derived from which solute present in the original sample.

Numerous chemical reactions have been used to derivatize different classes of biomolecules in LC, usually with a high degree of success. However, the overall enhancement is always dependent on the particular tags used. That is, derivatization reactions that tag a specific site within the biomolecule sometimes lead to a single, and sometimes several, tags incorporated into the derivative. As a function of the tag, there

will be improved detector response, but perhaps much smaller chromatographic changes than with small molecules if the derivatization is carried out pre-column. Derivatizations are therefore often performed post-column. An ideal derivatization scheme would generate many derivatives from the original biomolecule, such as via enzyme amplification. This is already used to detect intact enzymes, but is used much less to detect proteins, peptides, nucleic acids, etc. Thus, the scheme described using post-column, microwave digestion of proteins, followed by a second post-column solution reaction with a FL derivatizing reagent (e.g. *o*-phthaldialdehyde, OPA), leads to many amino acids now detectable by FL methods. This is, perhaps, an ideal example of a general approach that greatly improves detectability of large molecules, such as via enzyme amplification for enzymes.

Offline versus Online Arrangements

It is also necessary to differentiate between offline and online arrangements (Table 2). In the offline mode the reactions occur away from the high performance liquid chromatography (HPLC) system, although there may be some examples that could be defined as either offline or online (e.g. in a sample vial in a carousel as part of an automated derivatization-injection system in LC). In the online mode the reaction chemistry occurs as part of the HPLC system, integrated into the instrumentation and analysis, and is time constrained and controlled. Thus there are four different and distinct types of derivatization approaches, or modes, for LC: (1) online, pre-column; (2) online, post-column; (3) offline, pre-column; and (4) offline, post-column (Table 2).

Pre-column versus Post-column Arrangements

The derivatization can be carried out in the pre-column or post-column mode, i.e. before or after the separation has taken place. In the post-column approach the derivatization reaction does not have to yield a single, stable product, provided that the reactions are reproducible. There are several serious disadvantages associated with this technique: (1) excess

derivatization reagent must not interfere in the detection process; (2) reaction kinetics need to be rapid to allow real-time detection; (3) additional pumps are needed for a nonpulsating supply of derivatization reagent; (4) reaction solvents must be miscible with the separation mobile phase; and (5) an efficient mixing of derivatization reagent with the column effluent is required.

Pre-column derivatization is an alternative approach to post-column derivatization. One of its advantages is that derivatization is independent of the mobile phase and the reaction kinetics are not limited. Apart from an increase in detectability, pre-column derivatization can also improve the selectivity and chromatographic resolution of the overall method. Excess reagent present in the reaction mixture must be chromatographically resolved from the analyte derivative peaks, and/or be physically or chemically removed from the sample solution prior to injection. If several analytes yield the same derivative(s), then these would not be separable, and it would be impossible to determine which analyte was originally present in the sample. For example, the use of a substrate that could react with several enzymes, pre-column, would then lead to exactly the same product(s), preventing absolute identification of the enzyme actually present in the sample reaction mixture. More derivatizations have been performed online, post-column, as opposed to online, pre-column, or even offline, pre-column, for the above reasons, at least in LC areas. It is also possible to perform derivatizations *in situ*, or within the mobile phase. In this case derivatization reagent is placed in the solvents used for the LC separation. After separation has occurred, the eluent from the LC column can be heated to cause the reaction to occur, prior to the final detection stage. Unlike the online, post-column mode of operation, this does not require the addition of a mixing tee, heating coil, reagent pump, or ancillary tubing after the LC column.

Offline, Pre-column Derivatization

Offline, pre-column derivatizations have no extracolumn loss of efficiency and no solvent or kinetic limitations. Derivatization can be conducted under flexible reaction conditions or with harsh reagents. Offline derivatization can be optimized for high reaction yields and minimum by-products. Derivatization solvents need to be miscible with the chromatographic mobile phase. Otherwise, the derivatization solvents have to be evaporated and the residue of derivatives redissolved in a solvent compatible with the mobile phase. Offline derivatization does not need to give 100% theoretical yields, as long as there is good sample-to-sample reproducibility. However,

Table 2 Derivatization placement in LC

Mode	Reaction sequence
Pre-column, offline	Derivatization away from LC— injection—separation—detection
Pre-column, online	Derivatization on the LC— injection—separation—detection
Post-column, offline	Injection—separation— derivatization away from LC— detection
Post-column, online	Injection—separation— derivatization on the LC— detection

nonautomated offline pre-column derivatizations require operator attendance and manual manipulations.

Online, Pre-column Derivatization

Online, pre-column derivatization is accomplished by incorporation of a derivatization reagent into the flow scheme of the LC. Since all of the derivatized products are injected into the LC, this mode of derivatization does not have the solvent dilution problem observed in offline derivatization. There are several requirements for the conduction of online pre-column derivatization: (1) good chemical and/or pressure stability of derivatization reagents in organic solvent; (2) good solubility of derivatized products in the mobile phase; (3) no precipitate or gas generated in the derivatization; (4) compatibility of derivatization solvent with mobile phase; and (5) minimum volume of derivatization solvent or well packed solid-phase derivatization column. In online pre-column derivatization, the extraction and clean-up of complex samples often becomes part of the chromatographic operation, which can be automatically (computer/microprocessor interface) performed via switching of valves. Preliminary sample handling is minimized and automated derivatization procedures tend to provide better reproducibility.

Offline, Post-column Derivatization

This is perhaps the most unwieldy derivatization approach of all (Table 2). It involves separating the analyte of interest from the LC eluent prior to detection, performing a solution or solid-phase derivatization away from the instrumentation, manually or automatically, and then detecting the final derivatized solution. Automation is difficult, reproducibility is less than ideal, and even accuracy and precision falter, at times, because of a lack of total automatability. Thus, this mode receives the least emphasis in the literature and the lowest recommendation of application.

Online, Post-column Derivatization

In this approach (Table 2) injection-separation steps are followed by online derivatization, using automated, fully online instrumentation and methods. This technique utilizes post-column reactors (low dead volume mixing tees, knitted open-tubular reactors, low dead volume reaction coils, etc.) in which the chemical reagents are introduced to the LC eluent. A delay time is needed (reaction dependent) to convert the analyte to product(s), and the entire solution, along with excess reagent(s), is introduced into the detector. This approach also allows for online liquid-liquid extraction, ion suppression (dual column ion chromatography), pH adjustment, organic

solvent addition, basic hydrolysis reactions, additional chemical reactions modifying the solutes prior to the derivatization step (e.g. oxidation of imidazole ring in proline and hydroxyproline for their assay by the OPA reaction), enzyme addition, and the use of post-column, immobilized reagents or enzymes. There are many chemical reactions that have been employed post-column online: sequential reactions, solid-phase/catalytic enhanced reactions (e.g. carbamate detection), microwave digestion of proteins, photochemical reactions, etc. However, there are severe constraints or requirements on the nature of the reagent solvent and solution that can be mixed with the LC effluent, detector transparency of such solvents, prevention of analyte derivative precipitation before detection, mixing of reagents with analyte, lack of mixing noise, need for additional instrumentation, mixing tees, connecting joints, and extra tubing connections. Nevertheless, at least in LC areas, this particular mode has been the most widely employed and applied.

Specific Recommendations for Successful Application of Derivatization in Liquid Chromatography

It is clear that there are numerous approaches to successful derivatization possible in various modes of LC, including reversed-phase, ion exchange, normal phase and hydrophobic interaction. There are perhaps too many choices as to which specific reagent will prove applicable for a new analyte, or how to best optimize and apply any given reagent, much less what might prove the optimal LC conditions for the final derivatives. A rational approach to derivatization for all LC is called for. Such rational designs for method development, optimization and validation in HPLC are available from the literature. A rational approach to developing, optimizing and then validating a derivatization method for LC is described below.

1. Know the structure of the analyte(s), what functional groups are present for tagging, and what types of reactions might be employed. A good knowledge of organic chemistry is needed and available at this stage. Some of the existing texts on derivatizations for HPLC should be utilized.
2. What are the requirements of the final derivatization-LC method? It is necessary to decide what detection limits are needed, what sample matrices will be analysed, what limits of quantitation must be realized, what resolution (sample dependent) will be needed, and so forth.

3. What is known in the literature about the LC of the analyte of interest, as a standard pure compound (without regard to sample matrices yet)? Are conditions reported for underivatized analysis, and what conditions have been already described and optimized? Could these be eventually utilized for simple derivatives of the original analyte? What modifications might be needed to resolve the analyte derivatives? Are any tagging methods already reported for GC or thin-layer chromatography (TLC) that might prove applicable in LC? What types of reagents have been described? What were the specific reaction conditions already optimized for this derivatization scheme?
4. Perform simple, test tube reactions on a standard of the analyte offline, away from the LC instrument, to optimize reaction conditions and to demonstrate the nature of the products formed, their number, derivatization yield, ease of product work-up prior to LC, etc. Utilize TLC, gas chromatography (GC), LC, and whatever other analytical tools are available to determine which reagents will tag the analyte, the nature of the products formed. Follow the optimization steps described below.
5. Optimize the derivatization conditions in terms of the usual reaction parameters: time, solvent, pH, temperature, catalysts. This can be performed univariately or multivariately, even using computer algorithms (simplex/multiple routines) to realize surface maps of conditions leading to optimal formation of the desired derivative. Whatever the optimization routine used, the final conditions need to be compatible with pre- or post-column LC reaction requirements (instrumental, solvents, mixing). Optimize reaction conditions and demonstrate formation of the desired derivative *before* introduction into the LC instrument.
6. Demonstrate the formation of derivative, nature of the derivative (structure), purity of standard derivative, per cent derivatization (yield), etc., using standard organic chemistry methods (elemental analysis, mass spectrometry, Fourier transform infrared (FTIR) and nuclear magnetic resonance (NMR) spectroscopy). What is the nature of the derivative obtained from the analyte? What is its exact structure, solubility, stability to various LC solvents, detection properties (UV, FL, EC), etc.?
7. How does the final derivatization approach change the possible ionization states of the original analyte? What modifications to the separation conditions of the original, untagged analyte must now be made to accommodate the nature of the derivatized species (e.g. ion exchange chromatography (IEC) changes)? Will the new tag(s) induce additional charges on the original analyte that will then affect LC mobility, migration times, resolutions, etc.? Will the tags induce unwanted hydrophobic properties to the tagged species affecting solubility, migration tendencies, resolution, efficiency and peak shape? How do we then accommodate such structural and physical/chemical property changes, how do we know what those changes really are before any LC methods development is pursued? Will the newly tagged species still permit host-guest complexation, such as with cyclodextrins, crown ethers and other complexation additives to the LC buffer?
8. Now utilize the standard derivative to optimize the LC conditions, again consulting the literature to determine if this derivative or an analogous structure has already been described along with specific LC operating conditions. Utilize those conditions or slight variations to realize optimized LC conditions for your standard derivative. This may require optimization by univariate or multivariate methods, perhaps using computer algorithms, varying one parameter at a time to generate a surface map demonstrating optimized conditions. This is similar to resolution maps in LC via DryLab from LC Resources. There are other computer programs in the literature that might prove useful in this area of LC separation optimization for the standard derivative.
9. Demonstrate analytical figures of merit with standard derivative, based in part on original method/assay requirements, such as linearity of calibration plots possible (UV, FL, EC), detection limits, limit of quantitation, accuracy and precision of quantitations possible, robustness of the LC conditions to small operational changes (pH, temperature, solvent, ionic strength, voltage applied, sample introduction, etc.), time per analysis, cost per analysis, instrument/method preparation, etc. This is still all derived for standards of the derivative, and not yet with actual analyte or samples.
10. Demonstrate analytical figures of merit with standard analyte, exactly as above, but now introducing the actual derivatization steps required to convert the original standard analyte into the derivative.
11. Demonstrate analytical figures of merit with actual sample containing *known* levels of analyte, including all method requirements: limit of quan-

titration (LOQ), limit of detection (LOD), linearity of calibration plots, ruggedness, robustness, reproducibility, repeatability, accuracy/precision of quantitations, time per analysis, cost per analysis and sample preparation requirements.

12. Validate final, optimized method with known samples containing known levels of analyte using double-blind spiking, standard reference materials (if available), comparison with currently accepted method on split, spiked samples (known levels), and finally interlaboratory collaborative studies. Assemble all final data in terms of accuracy and precision, reproducibility from laboratory to laboratory, repeatability within one laboratory, ruggedness from laboratory to laboratory, robustness within any given laboratory, all in terms of qualitative identification of analyte present, and then final quantitative information in terms of accuracy and precision of such measurements.
13. Write up final procedure and protocols for performing the final, overall derivatization-LC method, including the necessary sample preparation steps, isolation of analyte from matrix (if required) before derivatization, possible derivatization of analyte in sample matrix followed by isolation of derivative, or derivatization of analyte in sample matrix with direct injection of crude mixture into LC with minimal (if any) sample preparation (dilute/shoot). Include all possible procedures and reagents, chemicals, solvents and instrumentation needed for another laboratory to reproduce, repeat, and obtain valid results using the newer method in their hands/laboratories.
14. Distribute the final protocols and procedures to all those laboratories that participated in the interlaboratory collaborative studies, so that they can validate and demonstrate reproducibility of the overall optimized methods involving derivatization-LC operations and conditions.

Problems and Pitfalls in Using Derivatization in Liquid Chromatography

There are some potential problems and pitfalls in the routine use of derivatizations in LC. Major amongst these is the need to remove the excess reagent and/or its hydrolysis and thermal degradation products from the final derivatization solution prior to detection. This can be accomplished by an initial sample clean-up offline, and/or by addition of a large amount of

another reactive compound to consume all of the excess reagent to form a single known derivative easily separated from the analyte's derivative. Sometimes the LC conditions themselves may resolve the excess reagent and any of its hydrolysis/by-products from the desired derivative. Other approaches utilize a derivatizing reagent that, together with its hydrolysis/by-products, does not appear in the final chromatogram because it has very different detector properties from those of the analyte's derivative.

Another possible problem in utilizing derivatization involves a low per cent conversion to the desired derivative. This can be improved by forcing the reaction conditions, working at elevated temperatures for longer periods of time, invoking a suitable catalyst and by increasing the concentrations of analyte and reagent. Sometimes isolating the analyte from the sample on a solid support, followed by reaction with the usual derivatization solution, can lead to a much faster and more efficient reaction and conversion. In general the higher the per cent conversion, the easier it is to detect trace levels of analyte in complex matrices, such as biofluids.

Another problematic area has to do with reactions from other components in the sample mixture, besides that of the desired analyte, leading to a complex mixture of derivatives difficult to resolve by LC and/or detection methods. This can be improved by selectively isolating the analyte of interest from the sample matrix prior to derivatization, followed by the desired reaction conditions and introduction of the derivative into the LC system. This can more easily be accomplished by combining affinity LC with another LC mode, such as reversed-phase, so that the affinity step isolates the analyte of interest. This is then followed by a derivatization on the affinity support with the analyte immobilized, or initial elution of the analyte from this support, solution reaction, and then introduction into the second LC system. A simple, solid-phase affinity extraction column can be used to isolate the desired analyte from the complex sample, and prepare it for the desired, homogeneous (solution) or heterogeneous (solid-phase) derivatization reaction.

Yet another possible pitfall has to do with the formation of several derivatives from the analyte, rather than the usual (desired) production of a single, homogeneously tagged derivative. It is usually desired to form a single, homogeneous derivative with good chromatographic and detector properties. However, if there are several possible reactive sites on the analyte, then it is always possible that more than one product will result. This can be avoided by using reaction conditions that force all sites to be tagged,

leading to a single product, or by preventing some of the sites from reacting by using suitable reaction conditions or protecting groups that will then leave only a single site left to react. In the case of protein or biopolymer derivatizations, multiple products are usually formed, leading to several LC peaks that then raise detection limits and make identification of the original protein and quantitation more difficult, especially at trace levels. In general, homogeneous (uniform) tagging of biopolymers is always problematic, though conditions are currently being developed that may eliminate such difficulties.

It is possible that the reaction conditions required for derivatization may cause the analyte itself to degrade, even as it reacts with the reagents. The degradation products can also react with the very same tagging reagent. This leads to a multiplicity of products, rather than a single homogeneous derivative, again making quantitation at trace levels and identification of the original analyte more difficult. However, this complex mixture of products can be forced to elute as a single, sharp peak by using suitable LC conditions. This can then function as a suitable peak for quantitation and identification of the analyte of interest.

Finally, there are the issues of reagent stability, purity, uniformity and shelf-life, all important areas when using a reagent over a long period of time for numerous analyses. Conditions must be found that provide a pure reagent with good shelf-life, long-term stability during the course of the reaction and storage, available from several commercial vendors at reasonable cost and amounts, and available in high purity and consistency. In most cases, such commercial reagents are indeed available for many LC applications today.

Conclusions and Summary

This article has provided an overview of derivatization for LC. It is clear that this approach has undergone significant developments over the past few decades, to the point where it is now a mature area of LC science. Numerous books and reviews have appeared in recent years, and the literature continues to grow. Several excellent primers are available on the use of derivatization in LC and other separation areas, such as capillary electrophoresis (CE). Derivatization serves several useful functions in LC, but can especially improve chromatographic performance and peak shape for the original analyte, improve detector response to permit trace determinations, and improve quantitation for the original analyte by improving signal-to-noise ratios in complex sample matrices.

Derivatization can also stabilize an otherwise reactive analyte by the formation of a more stable derivative. The formation of multiple derivatives, using either solution or solid-phase (mixed-bed) approaches, has enabled improved qualitative identification of an analyte, as well as confirmation of quantitation by providing two to three different peaks for such purposes, all from the same sample undergoing one or a series of tagging reactions. Automation of derivatization, both pre- and post-column and online or offline, has developed such that it has become virtually a routine part of LC analysis. It is quite common to perform derivatization of amino acids pre-column, offline or online, in order to improve the identification and quantitation of these species, for example in a protein hydrolysate or intravenous solution. Derivatization for trace level detection of many analytes has also become commonplace, particularly when combined with preconcentration as part of the sample preparation-derivatization-LC steps. These tagging approaches permit the trace analysis of many analytes in complex sample matrices that otherwise would not be detectable by direct LC analysis.

Derivatization has thus become very commonplace in much of LC analytical work and applications. A wide variety of suitable reagents are commercially available, providing enhanced detection in several modes (UV, FL, EC and MS). Derivatization approaches are being developed for proteins and peptides that would lead to directed fragmentation and/or improved ionization for lowered detection limits in various forms of mass spectrometry or LC-MS. These efforts to develop improved derivatization reagents for further LC-detector applications will undoubtedly continue for many years to come.

Introduction

The role of radicals in (bio-)chemical reactions is currently becoming increasingly significant. Free radicals may be generated by any kind of irradiation and contribute essentially to many aging processes in many materials, particularly in the presence of oxygen. They are even able to cause manifold organic damages as in lipid peroxidation or in inflammatory diseases. Organic reperfusion injuries after ischaemia are currently the subject of intensive research activities. On the other hand, stable free radicals are used practically in a number of applications in many fields, e.g. as additives in industrial processes such as polymerization or as analytical tools in research on membrane, emulsion and surface properties of materials or formulations. The utilization of such substances as protective additives, e.g. for process control or as research tools, has stimulated interest in the synthesis of new compounds of this class. The increasing search for radicals is paralleled with a rising demand for methods to detect, identify and quantify them. In the context of separation techniques, this means having a technique at hand to trace them in eluted fractions.

High chemical reactivity combined with low specificity is typical of the majority of radicals. As a consequence, solutions containing such substances are likely to alter their composition within a short time owing to the decreasing content of reactive components and to the accumulation of reaction products. This kind of change can easily be monitored by chromatographic methods. Having separated all the constituents at a given time, it may become necessary

to identify original or intermediate radicals to evaluate the particular stage of an ongoing reactive process. However, the detectors routinely used in HPLC cannot indicate directly any radical present in the separated fractions. The most advanced method suitable for this purpose is electron spin resonance spectroscopy (ESR), but most ESR spectrometers are currently installed as large and heavy instruments, not at all suitable as detectors for chromatographic methods. It will be shown here that this kind of spectroscopic method can be realized with devices of table-top size that can easily be integrated into any chromatographic separation line.

Electron spin resonance (or electron paramagnetic resonance, EPR) spectroscopy is the only direct method to measure radicals since it is based on the existence of unpaired electrons. Likewise, paramagnetic metal complexes are also sensitive to this spectroscopic method. A substantial advantage for the study of radical reactions would be the rapid analysis of a fraction directly upon separation to avoid changes caused by putative consecutive reactions. This can only be achievable by direct coupling of the separator (HPLC) with the specific detector (ESR) in the shortest possible way without any unnecessary dead volume (long tubing lines or valves). An absolute prerequisite for such an instrumental set-up is a spectrometer of a size that allows installation at the site of the sample separation, and not necessarily vice versa. The other problem is synchronization of sample separation and recording of a spectrum which requires a definite period of time. Both problems have been solved in the on-line coupling of HPLC and ESR spectroscopy described here.

ESR Spectroscopy as Detector

An introduction into the principles of ESR (or EPR) spectroscopy can be found in most textbooks on physical chemistry or in specialized monographs. Since this spectroscopic technique is rather uncommon

Figure 1 Alignment of an unpaired electron in a magnetic field.

in the field of separation sciences, a brief description of the principle is given here.

Electron spin resonance was detected by the Russian scientist Zavoisky in 1946 while researching the paramagnetic properties of matter. Radicals and metal complexes with an odd number of electrons in d-orbitals show paramagnetism since unpaired electrons generate local electromagnetic fields. They can be detected whenever they interact with an external magnetic field. This interaction can be understood in the way that the external field forces any unpaired electron to align (Figure 1).

Once in line with the parallel magnetic field, lines of a given strength the electrons are able to flip into the opposite direction while absorbing energy. The stimulating energy ($\Delta E = h\nu$, h is Planck's constant and ν is the frequency) to cause such a flip over must be of a frequency able to resonate with the unpaired electron tumbling in the magnetic field like a spinning top (Larmor frequency). This frequency again is linearly dependent on the applied magnetic field; in other words, the stronger the field, the higher must be the frequency of the energy to stimulate the flip over of a single electron. ($\Delta E = g\mu_B H$ where μ_B represents the Bohr magneton, H the external magnetic field and g is a dimensionless proportional factor, ~ 2 for a single electron, the so-called Landé factor. The whole term is part of the Hamiltonian operator which is used to describe the state of energy of a given system.)

In essence, the alignment of an unpaired electron in an external magnetic field can have two directions, either with the field (low-energy state) or against the field (high-energy state). This is the same kind of energy splitting (Zeeman splitting) as in nuclear mag-

netic resonance (NMR) spectroscopy. The transition between these two states needs energy in the range of high-frequency radio waves or microwaves, depending on the strength of the applied external magnetic field. Nowadays, it is quite common to use a microwave frequency between 9 and 10 GHz (within the so-called X-band) which requires a magnetic field in the range of 300–400 mT. To find the exact absorption energy of an unpaired electron, e.g. in a radical at a given strength of the applied magnetic field, two ways are possible in principle: either to scan the microwave at a fixed magnetic field, or vice versa, to scan the magnetic field at a fixed wavelength. Since it is technically much easier to vary the magnetic field rather than to tune a microwave source over a large range, ESR spectra are recorded by scanning the external magnetic field. They are commonly displayed as first derivatives which is different to all other spectroscopic techniques where absorption peaks are shown.

Interactions of unpaired electrons with surrounding paramagnetic nuclei result in additional splitting of energy levels (hyperfine splitting) that become visible as multiples of absorption lines. In some cases, different radical moieties can be identified by their individual hyperfine splitting structure.

Coupling between Radical Separation and Detection

The application of ESR spectroscopy as a detector in a separation technique like HPLC raises a number of problems which have been solved in the following way.

ESR Spectrometer Size

Common ESR spectrometers have a large magnet which makes the instruments rather heavy, up to half a ton in weight. However, newly developed ESR spectrometers have been reduced to a size comparable with commonly used diode array detectors.

Flow Conditions of HPLC Mobile Phases

Owing to the properties of the microwave, the sample size is geometrically restricted to a thickness of 0.3 mm, allowing only a total sample volume of some 50 μL (if the fluid phase contains water, the volume could be larger otherwise). The sample cuvette (a quartz flat cell) is located in a fixed position inside the instrument having open access from the bottom and top allowing tubing to be attached to fill the cuvette upwards and to flow out at the top of the instrument. This vertical flow direction of the mobile phase helps to avoid accidental trapping of gas bubbles that could spoil any spectral measurement. At a flow of 1 mL min^{-1} no turbulence occurs at any site within the sample cuvette ensuring homogeneous filling and flushing without any problem. The use of capillary tubing minimizes the dead volume between the common UV/visual light monitor and the ESR spectrometer and thus the flow delay between these two devices.

Tubing Material Required for Radical Detection

In all cases, non-metal tubing is used. It should be noted that steel capillaries can never be used in the vicinity of the magnetic field of the spectrometer. Moreover, it is advisable to avoid any metal surface at all when working on free radicals. Particularly if oxygen is present, even minute amounts of iron, for example, may be sufficient to catalyse the Fenton reaction.

Synchronization of Separation and Detection

A major problem to be solved is synchronization of the continuous sample flow from the chromatographic equipment and the scan time required for taking an ESR spectrum. This subject has already been tackled by a number of authors. However, problems regarding signal separation and measurement sensitivity remain. A typical ESR scanning time is one minute for a spectrum and this may be in conflict with the elution time of a single fraction from a HPLC column. Since complete chromatograms usually take some 8–15 min, single fractions are likely to take less than a minute to elute so no constant conditions can be expected in the sample cuvette while a spectrum is running. Simply stopping the flow for the time of recording a spectrum may result in local diffusion, causing a loss of resolution in the separation step, so

this approach is not recommended. Pulsed short-time spectra (FT-spectroscopy) are very sophisticated requiring a much more complicated instrumentation, so the 'cw' (continuous wave) technique still remains the current standard method.

Instrumental Arrangement and Operation

A practical solution that allows both continuous flow from the HPLC column and a resting period of a sample fraction in the ESR spectrometer cuvette is depicted in Figure 2. In principle, a shunt is provided to short-cut the passage through the ESR spectrometer. It is opened while an ESR spectrum is in progress and closed at any other time. This allows the cuvette to be filled with a fraction, to leave it for the time of scanning a spectrum, and to flush the sample upon completion. A disadvantage of this procedure is that it does not allow spectra of fractions running closely together to be obtained since the spectrum of the first sample is still being recorded while the second one is starting to elute from the column. In this case, it is necessary to repeat the chromatographic separation step for the second fraction of interest.

In order to control the flow either through or bypassing the ESR spectrometer, a T-connector is inserted into the tubing between the HPLC detector and the ESR spectrometer for branching off to the shunt. Both the outlet tubing from the spectrometer and the shunt are connected to a valve which alternately opens or closes either way. This arrangement has two major advantages: on the one hand, unnecessary and irregularly shaped dead volume that may disturb the sample flow from the HPLC device to the spectrometer is avoided by placing the control valve after both devices, and on the other hand, it is not possible to close off both paths by control error, thus minimizing the risk of accidentally building up destructive pressure in the tubing system. In a simple set-up, the valve can be operated by hand via an electrical switch. The delay time from the appearance of the peak of interest in the monitor system of the HPLC to the moment of filling the ESR cuvette with the corresponding fraction can be measured exactly and is highly reproducible. In more standardized or routine applications, automatic control is possible. This whole arrangement makes the ESR spectrometer truly an additional HPLC monitor that analyses radicals.

Supplementary Equipment

In some cases substances may turn into (short living) radicals after stimulation either by light irradiation or in the course of a reaction triggered by an added reagent. In other cases, reactive and short-lived radicals may be trapped in an adduct with a so-called

Figure 2 Instrumental set-up of synchronized online HPLC-X-band-ESR coupling (modified in accordance with Osterloh and Kroll (1998)).

‘spin-trap’. To provide the possibility for monitoring such reactions online with an eluted fraction, certain supplementary equipment may be added to the whole instrumental set-up as shown in Figure 3.

Application Examples

The following practical examples should demonstrate the advantages in detection of free radicals in HPLC

Figure 3 Attachment of supplementary equipment to the ESR spectrometer as radical detector.

direct and online by ESR. One deals with separation of a synthesized product, while the other deals with a reactive, short-lived radical species.

Synthesis of Stable Radicals

Stable radicals such as nitroxyl compounds become increasingly of interest for process control of radical reactions, e.g. polymerization. This practical example demonstrates both the complexity of sample composition after such a synthesis and the changes owing to the instability of a single component. The starting point here is a cleavable biradical which decomposes immediately in aqueous solution.

Chemicals: 3-PCA-anhydride [II] was synthesized by the method of Gallez *et al.* using PCA [I]; 3-carboxy-2,2,5,5-tetramethylpyrrolidine-1-oxyl and DCC (dicyclohexylcarbodiimide) (Figure 4).

Figure 4 Synthesis scheme for PCA anhydride using DCC in purified methylenechloride.

Figure 5 Chromatogram of synthesis product obtained by means of online coupled HPLC-ESR.

HPLC: Merck-Hitachi-HPLC with DAD (diode array detector), RP-18 (5 μ m) column (125/4 mm) and methanol-water solutions (flow rate 1 mL min⁻¹, pH 7, isocratic as well as gradient mode).

ESR: Miniscope MS-100 desk X-band spectrometer (Magnettech GmbH, Germany). GC-MS, IR and NMR-techniques were also used for the identification of unknown products.

In following the synthesis, mixtures of PCA anhydride [II] were investigated by online coupled HPLC-ESR. This anhydride in practice represents a suitable tool for the spin labelling of macromolecules such as albumin. The purified synthesis product was analysed. In contrast to the available

literature, the chromatogram obtained showed four ESR-active compounds after HPLC separation (Figure 5).

These were the PCA anhydride [II] (peak 3 with $t_R = 4.95$ min) and PCA [I] (peak 1 with $t_R = 1.39$ min) as expected as well as two new paramagnetic compounds with typical ¹⁴N-hyperfine coupling (peak 2 with $t_R = 3.34$ min and peak 4 with $t_R = 7.41$ min). Further, ¹H-NMR, IR and GC-MS experiments showed the compound with $t_R = 7.71$ min (peak 4) to be PCA dicyclohexylurea- amide. No other peaks gave an ESR signal.

Figure 6 represents the ESR spectra of the sample before and after chromatographic separations. Spectra of peak 1, 2 and 4 show a line triplet typical

Figure 6 ESR spectra of the initial substance and four separated paramagnetic compounds.

Figure 7 Scheme of formation of stable radicals in biological systems using PBN.

for nitroxyl radicals owing to the interaction between the unpaired electron and the nitrogen nucleus. The uneven number of protons and neutrons results in nuclear spin quantum numbers of -1 , 0 and $+1$, in equal distribution. Those nuclei with a spin different from 0 cause a magnetic field recognized by the unpaired electron in addition to that generated by the magnet of the spectrometer. The result is a hyperfine splitting into three spectral lines as shown in the respective spectra. Peak 3 comprises the biradical PCA anhydride [III] with two nitroxyl groups in close vicinity. The ESR spectrum is determined by additional interactions between these two radical moieties. All the single spectra of the separated peaks add to the composite one seen with the initial unseparated sample.

Common Radical Analysis

A typical characteristic of most radicals is their high reactivity so they normally have a short life. As a consequence, they may be present only in rather low concentrations so they may be difficult to analyse. Therefore, the spin-trapping technique was developed to detect short-lived radicals. **Figure 7** shows an example of this technique in which the reagent PBN (α -phenyl-*N*-*t*-butylnitron; not itself a radical)

forms a stable adduct with a reactive, short-lived radical. The highly reactive compounds analysed here are inherently linked to the aging process in living tissues.

The spectrum in **Figure 8** shows, in addition to the hyperfine splitting owing to the nitrogen nucleus (a_N), an additional one caused by the hydrogen nucleus in the β -position to the unpaired electron (a_H). This spin trap does not necessarily allow differentiation between radical species so combination of a separation step with the spin trapping reaction could provide this kind of information.

Conclusions

The simple and straightforward coupling of HPLC and ESR causes problems owing to the necessity to synchronize the chromatographic and the spectroscopic techniques. The first example presented shows that it is impossible to distinguish between more than two similar paramagnetic compounds with either technique alone. Therefore, the direct combination of both techniques requires additional equipment to solve the problems encountered. The second example demonstrates a tool to identify low concentrations, but highly reactive radicals, in separate fractions.

Our modified online HPLC–ESR coupling technique represents a suitable tool to solve such problems without any significant time lag with a high signal sensitivity comparable to conventional cw-ESR. Furthermore, the technique presented prevents severe problems that frequently occur in stop-flow chromatographic applications.

Detectors: Evaporative Light Scattering

R. P. W. Scott, Avon, CT, USA

Copyright © 2000 Academic Press

The evaporative light-scattering detector evolved from the early work of Charleworth and MacRae. The device consists of a spray system that continuously atomizes the column eluent into small droplets. The droplets evaporate, leaving the solute as fine particulate matter suspended in the atomizing gas. In practice, the column eluent passes into a concentric nebulizer where it is nebulized in a hot stream of gas that may be air or, if so desired, an inert gas such as helium or argon. The suspended particulate matter is then made to pass through an intense light beam from a source such as a helium–neon laser. The light scattered by the particles is viewed at 45° to the incident beam by means, for example, of a pair of properly placed optical fibres. The scattered light that enters the fibres is transmitted to a photomultiplier, the output of which is electronically processed and passed either to a computer acquisition system or to a potentiometric recorder. The evaporative light-scattering detector might be considered to be a form of transport detector where the transport medium is the nebulizing gas. A diagram of the light-scattering detector is shown in **Figure 1**.

The column eluent enters the centre orifice of a dual, concentric jet nebulizer where it meets a heated stream of nebulizer gas from the surrounding annular orifice. The gas flow rate is adjusted to provide a jet velocity that is just above the speed of sound. The stream of droplets that are produced normally have a relatively wide range of size distribution and pass down a heated tube, called the drift

tube. In this tube the solvent evaporates, leaving the solute as residual solid particles still carried in the gas stream. It is clear that this type of detector cannot function effectively if solid involatile buffers are used in the mobile phase. After passing through the laser beam, the gas containing the solvent vapour and particles is aspirated through a simple water pump which safely disposes of both the solvent vapour and the solutes. The laser is employed as a convenient source of high intensity light and its coherence does not appear to confer any particular advantage on the detection system.

The amount of scattered light that is collected is related to the diameter of the particles, the wavelength of the incident light and the angle at which it is collected. It is not linearly related to the concentration of solute in the mobile phase, but varies as either the power or the exponent of the solute concentration. For a given set of operating conditions the droplet size will remain sensibly constant during the development of a chromatogram. Now the average diameter of the solid particles produced will be the average size of the droplets multiplied by the cube root of the solute concentration. Thus, if the solute has a concentration of $10^{-6} \text{ g mL}^{-1}$, the solute particles will be 100 times smaller than the size of the droplets and, assuming a common value for the mean diameter of the droplets of $20 \mu\text{m}$, the solute particles will be $0.2 \mu\text{m}$ in diameter. Thus the mean particle diameter is of approximately the same order of magnitude as the wavelength of the scattered light.

Physical Properties of the Nebulizer

The intensity of the scattered light will be determined, among other factors, by the diameter of the solid

Figure 1 An evaporative light-scattering detector.

particles which in turn will be controlled by the size of the droplets generated by the nebulizer.

The average diameter of the droplets (D_0) in micron that is formed in a concentric nebulizer is given by the following equation:

$$D_0 = \frac{A\sigma_1^{1/2}}{u\rho_1^{1/2}} + B \left(\frac{\eta^1}{(\sigma_1\rho_1)^{1/2}} \right)^{0.45} \left(\frac{1000Q_1}{Q_g} \right)^{1.5} \quad [1]$$

where σ_1 is the surface tension of the mobile phase, ρ_1 is the density of the mobile phase, η_1 is the viscosity of the mobile phase, u is the relative velocity of the gas and liquid streams, Q_1 is the volume flow of mobile phase, Q_2 is the volume flow of the nebulizing gas and A and B are constants, taking values of 585 and 597.

The relationship between the mean solid particle diameter (D_s) and the mean droplet diameter (D_0) is given by:

$$D_s = D_0 \left(\frac{c}{\rho_2} \right)^{1/3} \quad [2]$$

where c is the concentration of solid solute in the eluent, and ρ_2 is the density of the solid solute. Thus:

$$D_s = \left(\frac{A\sigma_1^{1/2}}{u\rho_1^{1/2}} + B \left(\frac{\eta^1}{(\sigma_1\rho_1)^{1/2}} \right)^{0.45} \left(\frac{1000Q_1}{Q_g} \right)^{1.5} \right) \left(\frac{c}{\rho_2} \right)^{1/3} \quad [3]$$

Now it is the magnitude of D_s , the number of particles per unit volume and the wavelength of the laser light that determine the intensity of light scattered at a particular angle to the incident beam.

Intensity of the Scattered Light

There are two types of scattering that can take place, Mie scattering and Raleigh scattering, both of which can take place in the present design of light-scattering detector. Raleigh scattering occurs when the particle diameter is significantly less than the wavelength of light and Mie scattering occurs when the wavelength of the light is considerably less than the particle diameter. If the nebulizer is efficient, the major effect will be Raleigh scattering and thus only this type of scattering will be considered here.

One of the early scientists to examine scattered light was Tyndall, who showed that the scattered light from small particles was polarized. He found that light scattered at right angles to the incident beam was completely linearly polarized and demonstrated that the effect was independent of the nature of the scattering media and depended only on the particles being sufficiently small.

Lord Raleigh gave a simple explanation as to why light scattered at right angles to the incident beam is completely polarized. Consider a beam of unpolarized light travelling along the x -axis impinging

on a spherical particle located at the origin of a Cartesian coordinate system. The light can be resolved into two linearly polarized components that can each act independently of the other. If the particle is small compared with the wavelength of the light, then there is a uniform instantaneous electromagnetic field over the particle. As a consequence the particle will become polarized in the direction of the field. The net result is to produce a dipole that will oscillate synchronously and in the same direction as the vibrating electric field. The oscillating dipole will radiate electromagnetic energy and this scattered radiation will be polarized in the same sense as the dipole.

Assuming the scattering direction is taken from the origin through the point defined by the polar coordinates r , θ and ϕ , then:

$$x = r \sin \theta \cos \phi; \quad y = r \sin \theta \sin \phi; \quad z = r \cos \theta \quad [4]$$

If the angle measured from the scattering direction to the dipole is ϕ then the intensity of the scattered wave at a distance r from the particle will be:

$$I = \frac{16\pi^4 a^6}{r^2 \lambda^4} \left(\frac{\epsilon_1 - \epsilon_2}{\epsilon_1 + 2\epsilon_2} \right) \sin^2 \psi \quad [5]$$

which, from the Lorenz-Lorenz law becomes:

$$I = \frac{16\pi^4 a^6}{r^2 \lambda^4} \left(\frac{n^2 - 1}{n^2 + 2} \right) \sin^2 \psi \quad [6]$$

Furthermore, if ϕ is 45° then:

$$I = \frac{8\pi^4 a^6}{r^2 \lambda^4} \left(\frac{n^2 - 1}{n^2 + 2} \right) \quad [7]$$

It is seen that the light intensity varies inversely as the square of the distance from the particle, which would be expected from the inverse-square law. Not so obvious is the inverse dependence of the scattered light intensity on the fourth power of the wavelength of the incident light. In practice, the equation does not precisely predict the intensity of the scattered light as there are a significant number of particles present that are not greatly smaller than the wavelength of the incident light.

The Performance of the Light-scattering Detector

The evaporative light-scattering detector has two major advantages over many other liquid chromatography detectors. Firstly, like all transport detectors, its

function is almost completely independent of the solvent used for chromatographic development, with the one proviso that all the solvents used must be sufficiently volatile. This provides a wide range of solvent choice, allowing unique solvents to be used that would be impossible with other types of detectors. Its second advantage is its catholic response, which is similar to that of the refractive index detector. Moreover, as opposed to the refractive index detector, the evaporative light-scattering detector readily tolerates gradient elution development.

However, there are also certain disadvantages to this type of detector and certain precautions that need to be taken in its operation. One safeguard is to use a $0.45 \mu\text{m}$ filter in line with the nebulizing gas supply to remove any dust particles that may get caught up in the gas flow. Foreign particles in the nebulizing flow will contribute noise to the system and, as a consequence, reduce the sensitivity or increase the minimum detectable concentration. In addition, the nebulizer and drift tube will need to be cleaned regularly to remove accumulated sample deposits. This should be carried out every few weeks: failing to do this will not only result in significantly increased noise, but also adversely affect analytical reproducibility.

Occasionally the central jet of the nebulizer carrying the column eluent will become blocked, particularly if high solute concentrations or sticky solutions are nebulized. A blocked nebulizer tube will result in increased back-pressure and, if another detector is employed prior to the evaporative light-scattering detector, then the increased pressure can burst the sensor cell. A pressure sensor should be placed prior to the nebulizer so the back-pressure can be continuously monitored. If this pressure suddenly increases above the normal operating pressure, then the nebulizer will need to be disassembled and cleaned. A relief valve fitted behind the nebulizer will also protect any other detector that is being used from damage.

The nonlinear response of the evaporative light-scattering detector is a more serious problem as it renders quantitative analysis more involved. Furthermore, as the response varies between different solutes, calibration curves must be produced for each substance that is to be determined. The results are usually curve-fitted to an appropriate polynomial or power function which can then be used to modify the peak height or peak area measurements obtained in the actual analysis.

In general, the response of the detector can be fitted to the equation:

$$y = ac^b \quad [8]$$

where y is the detector response, c is the concentration of solute in the eluent, a and b are constants.

Consequently, the curve relating $\log y$ against $\log c$ will be linear and the slope will provide the value of b . In practice, b is usually found to be less than 2, which is the value it would be if only Raleigh scattering was taking place.

The two main disadvantages to the evaporative light-scattering detector are its relatively poor sensitivity (or high minimum detectable concentration) and its nonlinear response to the concentration of solute. There are a number of different commercial detectors of this type available and the consensus of opinion is that the sensitivity (or minimum detectable concentration) is similar to that of the refractive index detector, i.e. about $3 \times 10^{-6} \text{ g mL}^{-1}$. This sensitivity compares unfavourably with that of the fixed-wavelength UV detector, *c.* $5 \times 10^{-8} \text{ g mL}^{-1}$, the fluorescence detector, *c.* $1 \times 10^{-9} \text{ g mL}^{-1}$ and that of the modified moving ribbon transport detector, *c.* $8 \times 10^{-8} \text{ g mL}^{-1}$. Nevertheless, the sensitivity of $3 \times 10^{-6} \text{ g mL}^{-1}$ is quite practical for use in liquid chromatography and, due to its near universal response and its solvent independency, the detector is popular for lipid analysis and for other materials that do not fluoresce or have UV chromophores.

Applications of the Light-scattering Detector

Some examples of the use of the light-scattering detector to monitor the separation of materials that normally require gradient elution for resolution, but are sometimes difficult to sense by other types of detector, are lipids, fatty acids and phospholipids. An example of a chromatogram obtained from a sample containing a mixture of general lipid-class solutes and monitored by the light-scattering detector is shown in Figure 2 (Table 1).

The sample size is rather high for general quantitative liquid chromatographic analyses but the column does not appear to be overloaded. The minimum detectable mass estimated from this chromatogram appears to be about 10 ng of solute. To some extent, this detector provides an alternative to the conventional transport detector as it detects all substances irrespective of their optical or electrical properties. However, modern versions of the conventional wire or ribbon transport detector are reported to have significantly greater sensitivity.

Figure 3 depicts the separation of a mixture of fatty acids. The C_{18} -bonded silica column was 25 cm long, 2.1 mm i.d. and packed with particles of 3 μm diameter. The flow rate was 0.4 mL min^{-1} and the sol-

Figure 2 The separation of some lipid-class materials monitored by an evaporative light-scattering detector. For key, see Table 1.

vents used were water and acetonitrile. The gradient employed is shown in Table 2 and is typical for a reversed-phase column.

The solutes are initially retained by dispersive forces between the solutes and the stationary phase and are progressively eluted as the dispersive character of the mobile phase is increased with the greater concentration of acetonitrile. The weights quoted appear to be the concentration of each solute in the sample injected 20 μL of solvent. It is seen that an excellent response is obtained and the chromatogram is quite suitable for accurate quantitative analysis.

The separation of some phospholipids is shown in Figure 4. The column was 10 cm long, 4.6 mm i.d. and packed with particles of silica 3 μm in diameter.

Table 1 Key to Figure 2

Peak	Compound	Mass (μg)	Retention time (min)
1	Cholesterol ester	5	0.717
2	Triglyceride	18	1.746
3	Cholesterol	10	4.687
4	Unknown		8.860
5	Phosphatidyl choline	10	10.028
6	Phosphatidylethanolamine	10	17.390

Figure 3 The separation of some fatty acids monitored by an evaporative light-scattering detector. Peaks: 1, capric acid (0.10 mg mL^{-1}); 2, lauric acid (0.03 mg mL^{-1}); 3, myristic acid (0.03 mg mL^{-1}); 4, pentadecanoic acid (0.02 mg mL^{-1}); 5, palmitic acid (0.03 mg mL^{-1}).

The flow rate was 1.25 mL min^{-1} and the solvents used were water, isopropanol and *n*-hexane. The gradient employed is shown in Table 3 and has obviously been specially developed for this type of separation on silica gel.

In this separation the solutes are largely retained by polar forces and are progressively eluted by increasing the proportion of isopropanol and water.

Table 2 Gradient for a typical reversed-phase column with solvents A (water) and B (acetonitrile)

	0 min	5 min	10 min	20 min
% B	77	80	90	95

Table 3 Gradient using solvents A (isopropanol), B (*n*-hexane) and C (water)

	0 min	7 min	15 min
% A	58	52	52
% B	40	40	40
% C	2	8	8

Figure 4 The separation of some phospholipids monitored by an evaporative light-scattering detector. Peaks: 1, cholesterol (0.15 mg mL^{-1}); 2, palmitic acid (0.25 mg mL^{-1}); 3, phosphatidylethanolamine (0.15 mg mL^{-1}); 4, phosphatidylserine (0.30 mg mL^{-1}); 5, phosphatidylcholine (0.15 mg mL^{-1}); 6, sphingomyelin (0.15 mg).

The strong polar solvents deactivate the stationary phase by preferential adsorption and this allows the strong dispersive forces between the solutes and the hexane to elute the solutes. Again, the weights quoted appear to be the concentration of each solute in the sample injected in $20 \mu\text{L}$ of solvent. It is clear that the detector is quite sensitive to these solutes and, again, the response and resolution are more than adequate for accurate quantitative analysis.

Conclusions

Although the evaporative light-scattering detector is mechanically somewhat clumsy, relatively expensive and has a nonlinear response and limited sensitivity, it still fills a need for an effective detector that can be used for certain classes of compounds that cannot be sensed by other detector types. In addition, as opposed to the refractive index detector that can also sense similar materials, it allows a free choice of solvent and easily tolerates solvent programming.

Detectors: Fluorescence Detection

R. P. W. Scott, Avon, CT, USA

Copyright © 2000 Academic Press

The process whereby molecules are excited by electromagnetic radiation to produce luminescence is termed photoluminescence. If the release of energy is delayed, or persists after the removal of the exciting radiation, then the substance is said to be *phosphorescent*. Signal persistence (even with a short but significant lifetime) limits the use of phosphorescence for liquid chromatography (LC) detection, because signal continuance will produce apparent peak broadening and consequent loss of resolution. If the release of electromagnetic energy is immediate, or stops on the removal of the excitation radiation, the substance is said to be *fluorescent*. In contrast to phosphorescence, fluorescence has been shown to be extremely useful for LC detection, and has provided some of the highest sensitivities available.

When light is absorbed by a molecule, a transition to a higher electronic state takes place and this process is highly specific for each substance. This is because radiation of a particular wavelength, or energy, will be absorbed by specific molecular structures. If electrons are raised, due to absorption of light energy, to an upper excited singlet state, and the excess energy is not dissipated rapidly by collision with other molecules or by other means, the electron will return to the ground state with the emission of light at a lower frequency. Under such circumstances the substance is said to fluoresce. In reality, some energy is always lost before emission occurs and thus, in contrast to Raman scattering, the wavelength of the fluorescent light emitted is always greater than the incident light. For further information on the theory

of fluorescence the reviews by Guilbault, Udenfriend and Rhys-Williams are recommended (see Further Reading section).

With the exception of certain electrochemical detectors and the mass spectrometer, the fluorescence detector affords greater sensitivity to sample concentration than other devices. In addition, the fluorescence sensor is less sensitive to changes in ambient conditions, e.g. temperature and pressure. The high sensitivity that is achieved is also partly due to the very low background light level and the consequent low noise level. The low noise level of the fluorescent detector is in contrast to those detectors that involve light absorption measurements, where the signal is superimposed on a strong background signal with a high noise level. The major disadvantage of fluorescence detection is that relatively few compounds fluoresce in a practical range of wavelengths. However, the scope of fluorescence detection can be extended by forming derivatives. For example, the reagents fluoropa (*o*-phthalaldehyde) and fluorescamine (4-phenyl-spiro(furan-2-(3H),1'-phthalan)-3',3'-dione) are both commercially available derivatizing reagents that can react with primary amines to produce fluorescent derivatives. One other minor disadvantage is the effect of molecular oxygen which, if present in the mobile phase, can cause significant fluorescent quenching. It is essential, therefore, for maximum and constant response, to degas the solvents by helium sparging before use.

Most fluorescent detectors are configured so that the fluorescent light that is sensed is emitted at an angle (usually at right angles) to the direction of the exciting incident light beam. This arrangement minimizes the amount of incident light that may provide a background signal to the fluorescent sensor. It follows that the fluorescent signal is sensed against

a virtually black background and hence provides the maximum signal-to-noise ratio. If necessary, the background signal can be further reduced by the use of an appropriate filter to remove any stray scattered excitation light that might be received by the sensor.

The fluorescence signal (I_f) is given by

$$I_f = \phi I_0(1 - e^{-\epsilon cl})$$

where ϕ is the quantum yields (the ratio of the number of photons emitted and the number of photons absorbed), I_0 is the intensity of the incident light, c is the concentration of the solute, ϵ is the molar absorbance and l is the path length of the cell.

It is clear that the solute concentration is a somewhat complex function of the intensity of the emitted fluorescent light. As a consequence, the signal from the photocell must be electronically modified to produce an output that is linearly related to solute concentration.

Fluorescence detectors vary widely in complexity. The simplest consists of a single wavelength excitation source in conjunction with a sensor that responds to light at all wavelengths (UV and visible). For certain applications, this simple form of fluorescence detector can be very sensitive and inexpensive. However, by restricting the excitation light to a single wavelength, and with no means of selecting the emission wavelength, the system has limited versatility. At the other extreme is the fluorescence spectrometer that has been fitted with a sensor cell of appropriate dimensions. This comprehensive fluorescence monitoring system is highly complex and versatile and allows both the excitation and emission wave-

lengths to be chosen. Furthermore, excitation spectra can be obtained at any fixed emission wavelength, or an emission spectrum can be obtained for any fixed excitation wavelength.

The Fluorescence Detectors

The Single Wavelength Excitation Fluorescence Detector

With the exception of the electrochemical detector, the single wavelength excitation fluorescence detector is probably the most sensitive detector generally available to LC but, as already stated, it is so at the cost of limited versatility. A simple form of the fluorescence detector excited by light from a single wavelength UV source is shown in **Figure 1**.

The UV excitation source is usually a low pressure mercury lamp which is comparatively inexpensive and provides relatively high intensity UV light at 253.7 nm. Many substances that fluoresce will, to a lesser or greater extent, be excited by light at this wavelength. The excitation light is focused by a quartz lens, through the cell. Another lens situated normal to the incident light focuses the fluorescent light through a circular mask on to a photocell. Typically, a fixed wavelength fluorescence detector will have a minimum detectable concentration at an excitation wavelength of 254 nm of $c. 1 \times 10^{-9} \text{ g mL}^{-1}$ and a linear dynamic range of 1×10^{-9} – $5 \times 10^{-6} \text{ g mL}^{-1}$. One of the disadvantages of the fluorescence detector is this rather limited linear dynamic range.

Detectors have been designed as a compromise between the expensive fluorescence spectrometer and

Figure 1 The single wavelength fluorescent detector.

the fixed wavelength detector. A typical example of this compromise is the fluorescence detector that utilizes the monochromator of a dispersive UV spectrometer in conjunction with light filters. It consists of a UV dispersion spectrometer fitted with a special absorption cell having reduced dimensions.

The small sensor cell ensures that the narrow peaks produced by high efficiency LC columns can be monitored without loss of chromatographic resolution. The wavelength of the excitation light is selected by the monochromator which will be within the normal UV range of the spectrometer (*c.* 200–360 nm). The excitation light passes through the cell and the fluorescent light, emitted at right angles to the path of the excitation light, is focused on to a photocell. Up to this point, the sensor system is very similar to that of the fixed wavelength fluorescence.

In most of these types of compromise detectors, appropriate light filters can be inserted between the sensor cell and the lens that focuses the emitted fluorescent light on to the photocell. In this way, the wavelength of the light monitored by the sensor can be selected by the choice of an appropriate filter. This, in fact, is a rather primitive way of selecting the emission wavelength. Nevertheless, the arrangement can be quite effective, and certainly eliminates

the need for a second monochromator and the added cost. The use of this type of detector in monitoring the separation of the *o*-phthalaldehyde derivatives of some amino acids is shown in **Figure 2**. It is seen that a very high sensitivity is realized and the integrity of the chromatographic resolution is well maintained.

The Multi-wavelength Fluorescence Detector

One form of multi-wavelength fluorescence detector consists of two monochromators: the first selects the wavelength of the excitation light, and the second disperses the fluorescent light, and provides a fluorescence spectrum, or allows the separation to be monitored at a selected fluorescence wavelength. The multi-wavelength fluorescence detector is shown in **Figure 3**. The detector comprises a fluorescent spectrometer fitted with a suitable absorption cell that can be used with high efficiency LC columns without degrading the resolution of the column. The spectrometer involves two distinctly different light systems. The function of the detector is easier to understand if the different light systems and the respective light paths are considered separately. The detector

Figure 3 The fluorescence spectrometer detector. ---, excitation light; —, fluorescent light.

comprises an excitation light system and fluorescent light system.

The excitation source (emitting light over a wide wavelength range, such as a deuterium lamp) is situated at the focal point of an ellipsoidal mirror, shown at the top left-hand corner of the diagram. The parallel beam of light is collimated to fall on to a toroidal mirror, which then focuses it on to the grating, shown on the left-hand side of the diagram. This grating is used to select the wavelength of the excitation light or it can be used to scan the complete range of excitation wavelengths and provide a corresponding excitation spectrum that is monitored at a specific fluorescent wavelength. The selected wavelength then passes to a spherical mirror and then to an ellipsoidal mirror, shown at the base of the diagram, which focuses it on to the sample. The excitation light path is mostly depicted on the left-hand side of the diagram.

In the centre of the diagram, between the spherical mirror and the ellipsoidal mirror, is a beam splitter that diverts a portion of the incident light on to another toroidal mirror. This mirror focuses the light on to the reference photo cell. The reference photo cell provides an output that is proportional to the intensity of the excitation light. The path of the fluor-

escent light is depicted on the right-hand side of the diagram. Fluorescent light, emitted from the cell, is focused by an ellipsoidal mirror on to a spherical mirror at the top right-hand side of the diagram. This mirror focuses the light on to a grating which is situated at about centre right of the diagram. This grating selects a specific wavelength of the fluorescent light to monitor, or can scan the fluorescent light produced by excitation light of a given and selected wavelength, and provide a fluorescent spectrum. Fluorescent light from the grating passes to a photoelectric cell which monitors the intensity. The instrument is complex and relatively expensive; however, for measuring fluorescence, it is extremely versatile.

The optical system allows the wavelength of the excitation light and that of the fluorescent light to be chosen to provide the maximum selectivity for a given solute or its fluorescent derivative. The use of this optimization procedure is demonstrated by the high sensitivity detection of the fluoropa derivative of neomycin shown in **Figure 4**. It is an excellent example of the selection of a specific excitation light wavelength and the complementary emission light wavelength to provide maximum sensitivity.

Figure 4 Detection of neomycin OPA derivative at an excitation wavelength of 365 nm and an emission wavelength of 418 nm. Column: Supelcosil LC-8, 15 cm \times 4.6 mm, 5 μ m particles. Mobile phase: tetrahydrofuran: 0.0056 mol L⁻¹ sodium sulfate–0.007 mol L⁻¹ acetic acid–0.01 mol L⁻¹ pentanesulfonate, 3:97. Flow rate: 1.75 mL min⁻¹. Post-column reagent: 1 L 0.4 mol L⁻¹ boric acid–0.38 mol L⁻¹ potassium hydroxide containing 6 mL 40% Brij-35, 4 mL mercaptoethanol, 0.8 g *o*-phthalaldehyde. Flow rate 0.4 mL min⁻¹. Mixer 5 cm \times 4.6 mm column packed with glass beads. Reactor 10 ft \times 0.5 mm knitted Teflon capillary tubing. Reaction temperature 40°C. Sample: 20 mL of a mobile-phase extract of a commercial sample. Excitation wavelength 365 nm; emission wavelength 418 nm. (Courtesy of Supelco Inc.)

The principle of optimizing excitation and emission light wavelengths to obtain maximum sensitivity for a multi-component mixture can be quite complex, as shown by the separation of some priority pollutants depicted in Figure 5. The separation was carried out on a column which was 25 cm long, 4.6 mm in diameter and packed with a C₁₈ reversed phase. The mobile phase was programmed from 93:7 acetonitrile–water to 99:1 acetonitrile–water over a period of 30 min. The gradient was linear and the flow rate was 1.3 mL min⁻¹. All the solutes were separated and the compounds, numbered from the left, are given in Table 1. The separation illustrates the clever use of wavelength programming to obtain the maximum sensitivity. The programme used is shown in Table 1.

The wavelength of the excitation light and that of the emission light was changed during chromatographic development to provide optimum fluorescent conditions, and thus maximum sensitivity, for each solute. This ensured that each solute, as it was eluted, was excited at the most energetic wavelength and then monitored at the strongest fluorescent wavelength.

It is seen that the analysis involves a somewhat elaborate wavelength programme; nevertheless, if the analysis is sufficiently important, it is readily justified. The system also provides fluorescence and excitation spectra, by arresting the flow of mobile phase when the solute resides in the detecting cell, and scanning the excitation and/or fluorescent light. (This is the

Table 1 Fluorescence detector programme

Time (s)	Wavelength of excitation light (nm)	Wavelength of emitted light (nm)
0	280	340
220	290	320
340	250	385
510	260	420
720	265	380
1050	290	430
1620	300	500

same technique as that used to provide UV spectra with the variable wavelength UV detector.) In this way, it is possible to obtain excitation spectra at any chosen fluorescent wavelength, or fluorescent spectra at any chosen excitation wavelength. Consequently, even with relatively poor spectroscopic resolution, many hundreds of spectra can be produced, any or all of which (despite many spectra being very similar) can be used to help confirm the identity of a compound.

The above spectrometric arrangement can be considerably simplified and much of the mechanical systems eliminated by employing a diode array sensing device for the fluorescent light. This allows the fluorescence spectrum to be recorded continuously throughout the development of the chromatogram. A specific excitation wavelength must be selected and this is achieved by employing the usual mechanical monochromator. Excitation spectra still need to be obtained by stopping the mobile-phase flow and scanning the excitation light.

Due to the high sensitivities achieved by fluorescence detection, the technique has proved very useful as a detection system in capillary electrochromatog-

raphy and capillary electrophoresis. High sensitivity is achieved by employing a high energy excitation source such as a laser, emitting light at an appropriate wavelength. A typical optical system for fluorescent detection in capillary electrophoresis and capillary electrochromatography is shown in **Figure 6**. A window is opened in the quartz capillary tube, by removing the polyimide coating from about a millimetre length of capillary tube. The laser beam is arranged to pass through the window and the fluorescent light, emitted normal to the laser beam and the capillary tube, is focused on to a photoelectric cell or photodiode array. A filter can be interposed between the capillary window and the sensor measuring the fluorescent light, to eliminate scattered incident light. The signal from the photo cell is electronically modified in the same way as the normal LC fluorescence detector.

Unfortunately, lasers which have suitable wavelengths for this purpose are somewhat limited. However, lasers of various types are continuously being developed and this offers great promise for the future development of this type of detector.

An example of the use of fluorescence to monitor an electrophoretic separation of the AQC fluorescent derivatives of phenylalanine, methionine and serine are shown in **Figure 7**. In this separation vancomycin was used as the chiral additive. The separation was carried out on a 30.5 cm fused silica capillary, 50 μm i.d., containing 0.1 mol L^{-1} phosphate buffer and 5 mmol L^{-1} vancomycin. The pH of the buffer was 7.0 and the electrophoretic voltage 5 kV.

Fluorescence detection is the most popular high sensitivity detection method presently in use in LC, and will continue to be so for the foreseeable future. The system is basically simple, easy to use and provides at least an order more sensitivity than the generally popular UV detector.

Conclusion

Although relatively few substances are inherently fluorescent, most can be made to form fluorescent derivatives by relatively simple derivatization procedures. In addition, with the aid of a suitable laser, the natural high sensitivity of the device can be greatly enhanced. The main disadvantage of the fluorescence detector is its limited linear dynamic range but since in most LC analyses high sensitivity is usually required for trace analysis, in practice this limitation is not found to be so important.

Introduction

Infrared (IR) light is the term given to electromagnetic radiation having a wavelength lying between 1 and 15 micron. In contrast to UV light, which is adsorbed when the light energy at a particular wavelength is equal to specific electronic transitions in the molecule, IR light is adsorbed when its energy is equal to

changes in the vibrational and/or rotational energy of a molecule. A molecule can be considered as being made from a number of spheres (atoms) joined by springs (chemical bonds) and thus can vibrate in a very complex manner. As a general rule, a polyatomic molecule containing (n) atoms will exhibit $(3n - 6)$ modes of vibration and a characteristic fundamental frequency (or wavelength) will be associated with each vibration mode. Both UV and IR spectra can be used for substance identification but, due to the many vibration modes that are possible,

there is considerably more fine structure in IR spectra and consequently, IR spectra are generally more useful and give less ambiguous identification.

In general, IR adsorption is much weaker than UV adsorption and thus much larger samples are required. In addition, most of the solvents that are used in liquid chromatography adsorb strongly in the IR region and thus there have been very few IR based LC detectors developed, and none sufficiently effective for general use. In practice, the liquid chromatograph is usually combined with an IR spectrometer as a tandem system to provide spectra of the eluted solutes for identification purposes and not primarily as a detector. The basic construction of the traditional IR spectrometer is similar to that of the UV spectrometer except that the optical components must be transparent to IR light and thus must be made of appropriate materials. In addition, due to relatively low sensitivity, the interface is usually some form of transport device that also concentrates the sample as well as removing any interfering solvent. There are two forms of IR spectrometer, the grating dispersion IR spectrometer and the Fourier transform IR spectrometer (FTIR). The dispersion instrument is rarely used today in conjunction with the modern liquid chromatograph and the FTIR-LC tandem instrument now dominates the LC/IR field. Consequently only the FTIR instrument will be briefly described.

The Fourier transform IR (FTIR) spectrometer involves relatively simple instrumentation but quite complicated data processing. Due to its basic design, the spectrometer monitors all the wavelengths coincidentally, and consequently, the FTIR spectrometer can scan samples much faster than the dispersive

instrument. This feature alone, makes the FTIR spectrometer highly suitable for tandem operation. A diagram of the basic system is shown in Figure 1.

Light from a broad band infrared source is collimated and passes into an optical system where it strikes a beam splitter consisting of a very thin film of germanium. 50% of the light passes through the film and is reflected back along its original path by a fixed mirror, where half of the light intensity (25% of the original light intensity) is reflected by the same beam splitter, through the sample cell, to the infrared sensor. The remaining 50% of the incident light is reflected at right angles to its incident path onto an axially movable mirror. Light from the moving mirror returns along its original path and again, half of the light intensity is transmitted through the beam splitter, through the sample cell, to the infrared sensor. As a result of this optical system, a quarter of the original collimated incident light from the source reaches the sensor from the fixed mirror and a quarter from the movable mirror. Because the path length of the two light beams striking the sensor will differ, there will be destructive and constructive interference, the system constituting a Michelson interferometer. As the movable mirror traverses its programmed path, it will produce a series of maxima and minima as all the different wavelengths generated by the source pass through conditions of constructive and destructive interference. These maxima and minima are continuously monitored by the sensor and recorded. It should be noted that the frequency of the waveform is controlled by the velocity of the moving mirror which will be selectable.

The interferometer actually takes a Fourier transform of the incoming signal. An example of an

Figure 1 The elementary FTIR instrument. Courtesy of Nicolet Inc., Madison, Wisconsin, USA.

Figure 2 A typical interferogram. Courtesy of Nicolet Inc., Madison, Wisconsin, USA.

interferogram obtained from the FTIR is shown in Figure 2.

The resolution of the interferogram does not appear to be very good. However, this is misleading as a one second scan from an FTIR instrument gives equivalent resolution to that of a dispersive instrument scanning for 10 to 15 min. In any event, the FTIR resolution can be improved still further by using repetitive scans and processing the sum. The resolution is increased proportionally to the square root of the number of accumulated scans, e.g. 16 accumulated scans would increase the resolution by a factor of four. Spectra accumulation also increases sensitivity which is a distinct advantage in tandem systems, as the available sample may be severely limited. A single scan may take about a second, thus scanning for four seconds would double the sensitivity. Tandem systems involving IR measurements would not be successful without the introduction of the Fourier transform IR spectrometer.

LC/IR Transport Interfaces

The first transport system to be used as a liquid chromatograph-spectrometer interface was introduced by Scott *et al.* for a liquid chromatography/mass spectrometer tandem system. Eventually, the transport concept was extended to LC/IR tandem instruments and the most effective LC/FTIR interface commercially available incorporated a solvent transport interface. One of the first LC/IR transport systems was developed by Kuehl and Griffiths. Initially, moving ribbon devices were used in a similar manner to that of Scott *et al.*, but were eventually discarded in favour of a rather crude, but effective, rotating disc transport system. Their final model consisted of a cup carousel containing potassium chloride

that actually acted as a fraction collector and thus was hardly an in-line interface. Depending on the speed of the transport process, many transport interfaces could be considered as automated off-line monitoring devices. Fast moving transport systems such as a wire or belt transport however, give the impression of being in-line devices although in principle, they are not. The LC/IR carousel had 32 cups fitted with a fine mesh screen and filled with potassium chloride powder. Carousel position was controlled automatically in three positions, where specific sampling activities took place. In position (1) the eluent passed onto the potassium chloride until the halide powder was saturated with mobile phase. In position (2) a stream of air was drawn through the packing to evaporate the solvent. In position (3) infrared light was directed through the dry halide, and the spectrum was taken. The carousel interface concentrated the solute and increased the sensitivity of the LC/IR combination. Unfortunately, with modern LC columns, many peaks can be eluted in a few seconds and so intermittent sample collection is unsuitable. The carousel interface primarily acts as a chromatographic 'memory'; all the eluted solutes are stored as a 'physical' chromatogram as localized masses, deposited on the transport medium. The first chromatographic memory was introduced by Karmen, who used a wire transport detector to accumulate each eluted solute onto the wire surface, which was then stored on a reel. Subsequently, the wire was passed continuously through the flame of an FID, to produce a record of the separation. The most effective LC/IR interfaces are directly or indirectly based on this principle.

Jino and Fujimoto employed a potassium bromide plate as the transport system which was used as the sample holder for the IR measurement. Plate rotation

was actuated by the detector signal and, at the start of a peak, the plate was moved to a new collection position. The disc moved on when elution was complete so that the sample was isolated at a specific position on the plate perimeter. A small bore column was used (flow rate $5 \mu\text{L min}^{-1}$) so the eluent fell onto the plate and the solvent either evaporated under ambient conditions or with the aid of an infrared heater. After the separation was complete a spectrum was taken by measuring the light transmitted through the dry deposit in the usual manner. Obviously, because of the solubility of the halide in water, aqueous solvents could not be used.

Gagel and Bieman employed an aluminium disc, on top of which was cemented a circular glass mirror to form a transporter with a reflective surface; it was used in conjunction with a simple nebulizer that deposited the sample on the surface. Their basic apparatus is shown diagrammatically in Figure 3.

The disc rotated continuously during separation, leaving a spiral trail of solid deposits on the surface of the reflective plate. Evaporation was accomplished by the nebulizer. The column eluent passed into a T, one

limb of which carried a flow of nitrogen gas. The gas and eluent passed out *via* a narrow nozzle in the third limb, which directed the spray onto the disc surface. After separation, the disc was placed in a modified total reflectance IR accessory. The disc was rotated, the surface scanned by the IR spectrometer, and the reflectance-absorbance spectra continuously collected. This LC/FTIR interface appeared successful, and functioned without significant peak dispersion or loss of chromatographic resolution. The minimum mass needed to provide a satisfactory spectrum varied with the characteristic absorbance of the substances being monitored. However, it was shown that between 50 and 100 ng of sample could provide a recognizable spectrum.

Gagel and Bieman modified the nebulizer to improve the deposition, to make it amenable to aqueous solvents by reducing spreading, and to concentrate the material into a smaller area. The modified jet design involved the use of two nitrogen streams. The column eluent was mixed in a high pressure mixing T with nitrogen under pressure and directed through a syringe needle to the deposition surface. The needle

Figure 3 The layout of the transport LC/FTIR apparatus developed by Gagel and Bieman. (Reproduced with permission from Gagel and Bieman, 1986.)

Figure 4 Results from the modified LC/FTIR interface demonstrating the overall sensitivity of the tandem instrument. (Reproduced with permission from Gagal JJ and Bieman K (1987) *Anal. Chem.*, 59(9): 1267.)

was situated inside another nozzle through which heated nitrogen was flowing. The new arrangement functioned well with aqueous solvent mixtures and the overall sensitivity of the apparatus was significantly increased. The sensitivity of the modified interface is demonstrated in **Figure 4**.

The peaks from the injection of different masses of phenanthraquinone are shown on the left. The peaks are curves relating the IR absorbance at 1678 cm^{-1} to scan number for samples deposited from 29% water in methanol. The ultimate sensitivity, defined as the mass of solute that would provide a signal to noise ratio of 2, was about 16 ng.

Solvent elimination is relatively easy with nonaqueous mobile phases but the majority of LC separations employ reversed phase columns and require mobile phases with a high water content. Poor volatility of such solvent mixtures, causes the deposits to be smeared into one another. This seriously impairs the separation. Water in the mobile phase also restricts the choice of the transport medium as it must be water resistant. A considerable amount of work has been carried out on nebulizer design to improve solute deposition and focus the material onto a smaller spot. Techniques that have been tried include thermospray and hydrodynamic focusing that employs a concentric gas flow to reduce the jet diameter by the Bernoulli effect. Different transport media have also been explored, including potassium chloride layers on the surface of a zinc-selenium metallic stage using diffuse transmission spectroscopy to obtain the spectrum of the deposited material. The deposition of

the eluent from a narrow bore reversed phase column, onto the surface of a linearly moving substrate, using a jet spray assembly as an interface, has also been developed. The immobilized chromatogram (actually a chromatographic memory) is analysed by moving the substrate linearly under an FT-IR microscope while collecting the spectra. Zinc selenide was found to be preferable to an aluminized reflective surface as a disc transport. An example of the disc system used to display a reversed-phase separation of some polynuclear hydrocarbons is shown in three-dimensional form in **Figure 5**. The sensitivity to pyrene at a signal to noise ratio of 2 was 13 ng.

The In-Line Flow Sensor

The alternative to a transport interface is an in-line flow-through cell, and in 1983 a micro IR cell, $3.2\text{ }\mu\text{L}$ in volume, that fitted directly into the IR spectrometer was described by Brown and Taylor. By using a small-bore column they achieved an overall increase in mass sensitivity of about two orders of magnitude, relative to that obtained from the standard 4.6 mm i.d. column. An FTIR spectrometer was used, but the actual sensitivity improvement was confused as the length of the small bore column differed significantly from that of the standard column. Consequently, the true sensitivity in terms of minimum sample mass that would provide an acceptable spectrum, could not be assessed accurately.

A different cell design cell for use with LC micro-bore columns interfaced with an FTIR spectrometer

Figure 5 A three-dimensional reversed phase LC/IR plot of the separation of some polynuclear aromatic hydrocarbons. (Reproduced with permission from Conroy and Griffiths, 1984.)

was described by Johnson and Taylor. It was claimed that the cell would reduce the detection limit (the minimum mass required to produce a useful IR spectrum) to about 50 ng. The flow cell design is shown in Figure 6.

The cell was formed crystalline calcium fluoride or potassium bromide in the form of a block $10 \times 10 \times 6$ mm. A hole 0.75 mm i.d. was drilled through it to carry the mobile phase from the column through the block and out to waste. The collimated IR beam passed through the block, normal to the cylindrical aperture and, in doing so, transversed

a section of the exiting eluent. A beam condenser was used to reduce the focal diameter of the beam to that of the hole. It was noted that the maximum signal-to-noise was obtained by summing the spectra from scans taken across the peak, between $\pm 1.53 \sigma$ of the Gaussian profile, as it passed through the cell. As a practical point of interest, it was found easier to modify optically the size of the IR beam to match the flow cell, than to construct a cell that would accurately match the dimensions of the IR beam.

Sabo *et al.* developed an attenuated total reflectance cell for both normal- and reversed-phase

Figure 6 Zero dead volume micro IR cell.

chromatography. The cell was made with cone shaped ends, from a cylindrical shaped zinc selenide crystal, and mounted in stainless steel. The crystal was blazed at 45° and consequently gave ten reflections during passage of the IR beam down its length. The incident beam was focused onto the cone face and the radiation leaving the crystal was focused onto the IR sensor. The cell volume was large, ca. 24 μL and thus would adversely affect the resolution of a small-bore column. Clear, identifiable spectra were obtained from a 100 μL sample, containing 2% of acetophenone and ethyl benzoate and 1% of nitrobenzene from on-the-fly spectra. However, this was not a very sensitive device compared with other LC/FTIR systems.

A rather complicated solvent extraction system was developed by Conroy and Griffiths for use with an LC/FTIR tandem instrument. It involved a process that continually extracted the solute from the column eluent into dichloromethane. The solution is dichloromethane was concentrated and dispersed onto a plug of potassium chloride powder. The residual solvent was evaporated, the sample scanned and a spectrum taken. This process is somewhat clumsy but it introduces a new concept for constructing LC/IR interfaces. Employing the same basic principle Johnson *et al.* constructed a rather unique extraction cell for use with an LC/IR tandem system by introducing the technique of segmented flow. The aqueous eluent from a reversed phase column was mixed with chloroform (with which the column eluent was immiscible) producing segmented flow. The extraction solvent (chloroform) was then separated from the segmented flow by means of a 'hydrophobic' (dispersive) membrane. There were two pumps, one for the mobile phase and the other for the extraction solvent, which could be either chloroform or carbon tetrachloride. The two streams were mixed at a T junction (post column) and formed the segmented flow. The segmented flow then passed through an extraction coil and then to a separator. The separator was made of stainless steel with a membrane having pores about 0.2 μm in diameter dividing its length into half and its general layout is shown in Figure 7.

The volume on either side of the membrane was about 16 μL and the amount of solvent passing through the membrane was controlled by the differential pressure across the membrane. Obviously this device could cause serious peak dispersion and would be unsuitable for use with high-efficiency of small-bore columns. Samples containing at least 300 μg of material were necessary to produce a satisfactory spectrum, indicating a relatively poor sensitivity.

The segmented flow interface was developed further by Hellgeth and Taylor, who improved both the

Figure 7 An extraction interface for LC/IR.

segmentation and the extraction efficiency. The segmented flow generator was made from 1/16 in. Swagelok T union, drilled out to contain 1/16 in. tubes the ends of which were only 0.45 mm apart and the general design is shown in Figure 8.

The column eluent and extraction solvent passed into the mixing T through tubes 0.020 in. i.d. The exiting segmented flow passed through an extraction conduit consisting of a TeflonTM tube, 75 cm long and 0.8 mm i.d. The membrane separator was constructed from two stainless steel plates with grooves in each surface, and a triple-layer membrane of Gore-TexTM sheet. The membrane was made from two materials. The inner layer comprised an unsupported 1 μm pore TeflonTM sheet which was sandwiched between two outer sheets of 1 μm pore TeflonTM. These sheets were supported by non-woven polypropylene membranes which were located on the outer surfaces. The infrared cell was a modified Spectra-Tech Inc. demountable flow cell fitted with windows of either calcium fluoride or zinc selenide. The system appeared to function reasonably well; satisfactory spectra were obtained from 100 μg of material. Although a considerable improvement, the sensitivity was still relatively poor compared with that obtained with the rotating disc transport interfaces.

Further work by Somsen *et al.* has resulted in a segmented flow concentrator with significantly reduced band dispersion. A conventional liquid chromatograph was employed. It included a pump, pulse damper, injection valve and column. The column eluent entered a T piece where it was joined by an immiscible extraction solvent, usually methylene dichloride, supplied from another pump and pulse damper.

Figure 8 Diagram of a phase separator.

The extraction solvent flowed through a second column situated prior to the T piece to provide more pulse damping. The segmented mixture then passed through an extraction coil which provided the necessary time for the solutes to diffuse from the aqueous phase into the solvent. There is no parabolic velocity profile in segmented flow, and thus little or no peak dispersion can occur.

The segmented flow entered a phase separator and the separated solvent then passed through a UV absorption detector and into a spray jet assembly. Heated nitrogen was used in the spray jet assembly, to aid in the nebulization process. The chromatograms obtained indicate that very little peak dispersion occurs and that the column resolution is not significantly degraded. The finite volume of the extraction tube, however, produced a significant retention delay (about 3.5 min), which varied with both the flow rate and volume of the extraction system. Providing the solvents were reasonably volatile, they were completely removed in the nebulizing process. However, the percentage of organic solvent in the mobile phase must not be large enough to make it miscible with the methylene dichloride and prevent the formation of segmented flow. It follows that the choice of mobile phase was somewhat restricted.

Conclusion

Although considerable work has been applied to the development of LC/IR, it remains the least effective of all the LC tandem instruments. However, the IR

spectrum does provide unique information not readily available from other spectroscopic techniques and consequently, for the elucidation of certain molecular structures, can be extremely useful, if not essential. It would appear that, at this time, the transport interface will provide the highest sensitivity and the best spectra if sample availability is limited.

Introduction

Liquid chromatography (LC) can often separate complex mixtures but simple detectors (e.g. ultraviolet-visible UV/Vis) do not allow identification of the individual components. Comparison of retention data and spiking with known standards is normally required to provide evidence of composition but this may lead to erroneous results as absolute identification is not possible. Development of diode array detection has somewhat alleviated the problem but not removed it entirely. Absorbance requires the presence of a chromophore in the molecule and, as such, UV/vis spectra do not enable absolute identification but are frequently used to confirm identity through comparison of recorded spectra with reference spectra.

Mass spectrometry (MS) provides a unique means of determining the presence of a compound in a mixture by producing a mass spectrum which will aid or confirm its identification. The relative molar mass (RMM) and/or structurally important information may also be obtained from the mass spectrum.

The combination of a separation technique with MS provides a powerful instrumental method for the analytical scientist. Modern gas chromatography-mass spectrometry (GC-MS) instrumentation, having overcome the obstacles associated with coupling them to each other, has matured into an easy-to-use benchtop technique. The interfacing of high performance liquid chromatography (HPLC) with a mass

spectrometric detector (LC-MS) poses many problems, not least the different sample requirements of the respective instruments, i.e. liquid and vapour. The purpose of this article is to describe those interfaces that are most routinely used in LC-MS applications and, as such, will cover aspects of ionization methods and, to a lesser extent, mass analysers.

Background

The combination of HPLC and MS can be used as an offline technique, that is, fractions are collected and then a mass spectrum of each obtained. Much greater sensitivity, however, may be achieved by having an online interface, but this is much more difficult to achieve than with GC. The vapour flow in HPLC is much greater than in GC and there may be problems with electrical breakdown in high voltage instruments. HPLC may be operated in either normal or reversed-phase modes and the mobile-phase composition may be either isocratic or gradient. Different-sized columns are available (analytical, microbore and capillary), leading to a wide range of operational flow rates. The various possible configurations complicate the interfacing to MS.

The development of LC-MS has a history of more than 20 years and many interfaces have been reported, although only a small number have become commercially successful. Each method has its advantages and disadvantages (i.e. there is no universal interface). All facilitate the transition of analyte from solution into the gas phase with either simultaneous or sequential ionization. Those interfaces that have stood the test of time and are (or have been)

commercially available have relied on a particular ionization method and this presented limitations to the range of compounds that could be handled. Until the early 1980s, the mainstay ionization techniques were electron ionization (EI) and chemical ionization (CI), both of which required the sample to be in the vapour state. Development of LC-MS was slow, due to problems of matching vacuum requirements with liquid flow. Early interfaces utilized direct liquid introduction, usually after splitting the LC eluate. Thermal evaporation of the fraction of the liquid taken into the MS was followed by either EI or CI, with the reagent ions being generated from the solvent in the case of CI.

Of the many interfaces that have been reported, those most commonly employed in present applications are based on the following: particle beam (monodisperse aerosol generator interface for chromatography or MAGIC), continuous flow-fast atom bombardment (CF-FAB), thermospray and atmospheric pressure ionization.

Ion Formation

Particle Beam

The original particle beam interface was introduced by Willoughby and Browner in the mid-1980s using the acronym MAGIC. It relies on the nebulization of the chromatographic eluent followed by desolvation and then ionization of the resultant microparticles. A schematic of a typical particle beam interface is shown in Figure 1.

The initial nebulization of the eluent is accomplished with the aid of a dispersion gas (usually helium); thus a fine and homogeneous aerosol can be generated from mobile-phase flow rates ranging from 0.1 to 2.0 mL min⁻¹. Several designs of nebulizer are available, some utilizing heat or ultrasound in addition to a gas, to create the aerosol. The resultant mixture of gas and solvent droplets passes directly into a desolvation chamber where the droplets are converted into solvent-free particles before reaching the exit nozzle. To aid faster evaporation of solvent

molecules, the temperature of the chamber is maintained slightly above ambient. Momentum separation of the resultant stream of gas, solvent vapour and solute microparticles occurs between the desolvation chamber and the ion source. This is achieved by a series of skimmers placed in line with the nebulizer jet and exit nozzle. Differential pumping is effected in the regions between the skimmers. Expansion into the lower pressure regions leads to the formation of a high velocity jet of solute microparticles. Most of the helium and solvent vapours are removed in these lower pressure regions, leading to solute enrichment. The solid solute microparticles enter a conventional EI/CI ion source and are rapidly converted to the gas phase by flash vaporization upon contact with the heated walls of the source. Subsequent ionization by electron impact or chemical ionization follows.

The particle beam interface offers the advantage of producing library-searchable mass spectra but there are limitations of volatility and thermal stability for the analytes. In common with most LC interfaces for MS, the use of involatile buffers is best avoided, as is the use of mobile phases with a high water content. Disadvantages of the particle beam interface lie in the lack of sensitivity compared to other techniques which rely on 'soft ionization' methods, but careful optimization can lead to detection limits in the nanogram range for full scan acquisitions and use of selected ion monitoring can improve this to picograms. The development of particle beam interfaces capable of operating at lower flow rates would enable an increase in sensitivity to be achieved.

Continuous Flow-Fast Atom Bombardment

This technique relies on ionization of the sample by FAB. In a FAB ion source the sample is bombarded by a beam of energetic (usually 8 keV) atoms, resulting in the production of ions via the phenomenon of 'sputtering'. This process, although not fully understood, may be viewed as a series of impact cascades through the uppermost layers of the sample, resulting in the ejection of neutral and charged particles from the sample surface. Inert gases (Ar or Xe) are used to produce the atom beam but it is now more usual to employ a beam of fast ions, usually Cs⁺, with energies up to 30 keV. This latter method is also referred to as liquid secondary ionization mass spectrometry (LSIMS).

The sample material is deposited on the end of a direct inlet probe along with a viscous liquid (matrix). The matrix is necessary to prolong sample lifetime as mass spectra produced from solid samples are transient. Ideally the liquid matrix (e.g. glycerol, m-nitrobenzyl alcohol) should be capable of dissolving the sample molecules, be inert and have a low

Figure 1 Simplified schematic of a particle beam interface.

vapour pressure. The ion source is normally operated at ambient temperatures and it is therefore possible to obtain mass spectra from thermally labile and/or involatile materials. Compounds of RMM up to 2 kDa are routinely analysed by FAB and it is possible to obtain mass spectra from larger molecules. FAB mass spectra generally show abundant ions of the type $(M + H)^+/(M - H)^-$, thus allowing RMM information. These even-electron species are relatively stable and there is not always sufficient fragmentation to be structurally informative. Chemical noise is often a problem in FAB mass spectra as it may obscure low intensity fragment ions, and peaks arising from the matrix may coincide with sample peaks, hindering interpretation.

CF-FAB (other variations are known as dynamic FAB or frit-FAB) employs either FAB or LSIMS to effect ionization. All rely on the introduction of liquid through a capillary that terminates at the end of a direct insertion probe (Figure 2). Different designs of probe tip have been developed but all require an even spread of liquid over the surface which allows the production of a stable sample ion current. The solution entering the ion source requires the presence of a matrix liquid, normally in the range 1–10% by volume, and this is usually introduced post-column for LC-MS applications. This reduction of the sample/matrix ratio may provide improved signal to chemical noise ratios and peaks associated with the matrix may be either absent or of low intensity. A reduction in the sample suppression effects observed in FAB may also result.

This is a very simple interface design and is applicable to many thermally labile and/or polar samples. The probe tip does require heating (up to 60–70°C) to maintain evaporation and prevent freezing due to latent heat of vaporisation. The prime disadvantage is the restriction imposed on flow rates which are in the

range 1–10 $\mu\text{L min}^{-1}$ and therefore a split in the column eluent is required for all but capillary columns. Splits may be achieved by a number of methods, involving the use of T-pieces, balanced columns and pneumatic splitters, either separately or in combination. Whatever method is employed, it should have low dead volume and provide a quick response to changes in solvent composition imposed by gradient elution.

Thermospray

Thermospray ionization is effected directly from a sample solution and may be readily interfaced with HPLC. The thermospray ion source, which was developed from direct liquid introduction interfaces, can accommodate a wide range of liquid flows (0.5–2.5 mL min^{-1}) but is limited to the use of volatile buffers. It is a soft ionization technique and produces mass spectra dominated by ions yielding RMM information, i.e. $(M + H)^+/(M - H)^-$, but modifications to the source have allowed a certain amount of controlled fragmentation to be induced.

The sample solution is carried into the source via a capillary tube which terminates in a heated block. This results in the formation of a supersonic jet of vapour which contains charged droplets, the charging of the droplets being aided by the presence of a volatile electrolyte (e.g. ammonium acetate). By a combination of ion evaporation and ion–molecule reactions, sample ions are formed and exit the source via a small sampling orifice. The excess solvent vapours are removed by a backing rotary pump. In those situations where it is not possible or desirable to add a volatile electrolyte to the mobile phase, ionization may be effected by a mechanism akin to CI. This is achieved either by use of an electron beam (often termed filament on) or by creating a plasma within the vapour-rich source, usually by a high voltage discharge from a needle – a technique sometimes referred to as a plasmaspray. A simple schematic of a thermospray source is shown in Figure 3.

A wide variety of compounds are amenable to thermospray but its ability to cope with large, non-volatile molecules is poor and the mass range appears to be limited for routine use to compounds below ~1500 Da. The operating temperatures of the source must satisfy the requirement of efficiently vaporizing the sample but without thermal degradation. Positive and negative ions are often formed with equal facility but, in general, basic compounds are best studied in the positive ion mode: negative ion operation is more sensitive for acidic molecules. Lack of knowledge with respect to proton affinities often means that the best ionization mode needs to be determined experimentally.

Figure 2 CF-FAB probe tip.

Figure 3 Simplified diagram of a thermospray ion source.

Lack of fragmentation is often observed in thermospray mass spectra but application of a higher voltage to a repeller electrode (located opposite the sampling cone) may be sufficient to induce the formation of fragment ions.

Criticisms of the technique have centred on the claims of poor reproducibility and compound dependence. The performance and optimization of the interface depend on the solution chemistry and solutions must be kept free of particulate matter that may lead to blockage of the capillary. Despite some disadvantages, many applications of thermospray have been described and it has been the mainstay for LC-MS development for a number of years. However, recent advances in alternative ionization methods may well see it superseded as the method of choice for LC-MS.

Atmospheric Pressure Ionization (API) Methods

In the sources so far described, ionization takes place in the vacuum region of the mass spectrometer, thus requiring removal, either through additional pumping or by a reduction in the flow rate of the mobile phase. The production of ions prior to entry to the MS high vacuum regions, i.e. at atmospheric pressure, would obviate these requirements. Development of atmospheric pressure ionization techniques has led to a rapid and exciting development in LC-MS instrumentation. Although API methods have been available for a number of years, it was not until the pioneering work of Fenn *et al.* that their potential was realized. The two variants normally employed in conjunction with HPLC are electrospray ionization (ESI) and atmospheric pressure chemical ionization (APCI).

Electrospray ionization ESI produces charged particles directly from solution at atmospheric pressure. Since its introduction in the mid-1980s it has developed into one of the most popular ionization techniques, especially for biomolecules. The source design is relatively simple and extraction of ions into the mass spectrometer is readily achieved. Although a variety of source designs have been developed and commercial instruments differ in this respect, the

basic processes of ion information and extraction are similar.

In its simplest form, ESI is realized from a sample solution (flow rate $2\text{--}10\ \mu\text{L min}^{-1}$) introduced through a capillary into the ion source, which is at atmospheric pressure. The emerging liquid is formed into a fine spray of charged droplets by the presence of a potential difference of $\pm 3\text{--}5\ \text{kV}$ applied between the capillary and a counter-electrode. The formation of gaseous ions from the sample solution occurs as a result of this droplet formation and subsequent desolvation. Formation of the charged droplets is reasonably well understood, but the process of ion formation from them is the subject of debate.

A typical source is shown in **Figure 4**.

The capillary delivering the liquid flow is contained, in a co-axial arrangement, within an outer stainless-steel capillary. A flow of gas through this outer capillary aids droplet formation and extends the usable flow rate up to $\sim 1.5\ \text{mL min}^{-1}$. Nitrogen is the usual nebulizing gas employed in this modification, sometimes referred to as ion spray. Beyond the counterelectrode is a sampling cone (or in some instruments this may be a short glass or steel capillary) which may be maintained at a low voltage ($\sim 30\text{--}250\ \text{V}$). Between this cone and the counterelectrode, a countercurrent flow of gas (usually nitrogen) is introduced. This gas, known as the drying or curtain gas, aids the desolvation process. Additionally, the source may be held at elevated temperatures ($\sim 60^\circ\text{C}$) as a further means of helping desolvation. Entry into the analyser region of the mass spectrometer proceeds via a skimmer held at ground potential. Stages of differential pumping (or cryopumping) reduce the source pressure (atmospheric) to that of the analyser ($\sim 10^{-5}\ \text{mmHg}$).

Electrospray is an extremely soft ionization technique and results in the formation of ions representa-

Figure 4 Ion source for electrospray ionization. For operation in APCI mode, a discharge needle would be placed between the inlet capillary and the counter-electrode.

tive of the intact molecule with virtually no fragmentation. For small molecules the mass spectra have a very simple appearance, generally showing just the protonated molecule ion and/or adduct ions, e.g. $(M + Na)^+$. The mass spectra of larger molecules, however, become more complicated because of the production of multiply charged ions. A series of molecule ions of the form $(M + nH^+)^{n+}$ is produced, where n varies according to the number of sites on the molecule which are able to accept a proton. The molecular mass of a compound is calculated from the ion series by a deconvolution algorithm contained in the instrument's software (though it can be done manually!). An example of a typical ESI spectrum and the result of deconvolution is shown in Figure 5.

Formation of negative ions occurs in electrospray, with both singly and multiply charged species being formed. The choice of ionization mode depends on the proton affinities of the analytes.

In addition to molecular weight information, ESI mass spectra may contain ions representative of both specific and nonspecific interactions that are noncovalent in nature. Fragmentation of intact molecule ions may be induced within the source region by manipulation of the cone voltage. The application of a voltage (up to 250 V) between the counter-electrode and the first sampling cone will lead to low energy collisions between sample ions and the curtain gas. Depending on the energy of these collisions, declustering and then fragmentation may occur.

Figure 5 (A) ESI mass spectrum of cytochrome c; (B) deconvoluted mass spectrum of cytochrome c.

Since its introduction, ESI has undergone rapid development and has seen widespread application, especially in the biochemical field. Commercial instruments with dedicated ESI sources are readily available, ranging from simple benchtops to sophisticated tandem mass spectrometers.

The development of orthogonal sources has allowed the use of non-volatile buffers for LC-MS whereas 'in-line' sources are restricted to volatile buffers.

Atmospheric pressure chemical ionization An APCI source relies on the formation of reactant ions and their subsequent reaction with sample molecules. These reactant ions are formed at atmospheric pressure by a corona discharge achieved by maintaining a stainless-steel needle at a voltage of 3–6 kV. The source design for APCI, for LC-MS, is very similar to that of ESI, the major difference being the addition of the discharge needle in the region between inlet capillary and the counterelectrode. The LC eluent is converted into a fine droplet spray by a nebulizing gas and this is followed by vaporization in a heated region (up to 500°C, depending on the instrument) of the capillary. This rapid desolvation and vaporization minimizes any thermal decomposition. Chemical ionization of the sample is effected via ion molecule reactions: the reactant ions are formed from the LC mobile phase. Operation in either positive ion or negative ion mode is possible depending on the nature of the analyte. The use of a curtain gas aids declustering in a manner similar to electrospray. Molecular weight information is readily provided, but to obtain structural information the use of collision induced decomposition (CID) experiments is required.

Mobile phase flows from 0.1 to 2.0 mL min⁻¹ can be accommodated, eliminating the need for splitting. Both volatile and, with the advent of orthogonal sources, nonvolatile buffers are tolerated and mobile-phase compositions of up to 100% water are permitted.

Mass Analysis

All the above ionization techniques may be used in conjunction with different types of mass analyser, though the use of single or multistage quadrupoles is most common. The reader is referred to the chapter on GC-MS for a discussion of sector and quadrupole analysers.

Ion traps, time-of-flight and ion cyclotron resonance mass spectrometers have all been used in LC-MS instruments: a full treatment of them is beyond the scope of this article.

The ion trap is a device in which ions may be stored and consecutive experiments carried out upon them, i.e. mass spectrometry in time rather than space. Ions

may be produced directly in the trap, e.g. by EI (GC-MS) or they may be injected from an external source, e.g. ESI. Technological developments have ensured continued improvement to the mass range and resolution. The ability to undertake sequential CID experiments is a powerful feature of modern instruments. Dedicated LC-MS instruments employing ion traps in conjunction with ESI and APCI are now available.

Time-of-flight analysers are particularly well suited to pulsed ion sources, e.g. matrix-assisted laser desorption ionization (MALDI) and offer increased sensitivity over scanning instruments. Recently, pulsed orthogonal electrospray sources have been described in conjunction with time-of-flight.

The above method of mass analysis relies on the premise that, if ions of different masses leave the source at the same time, they will arrive at the detector separated in time. In practice, ions are accelerated into a field-free region (drift tube) with up to 20 keV energy. If all ions have the same kinetic energy then their velocity is dependent on their mass; thus, their time of arrival at the detector is different (light ions first). A pulse of ions is generated and the time taken for each ion to arrive at the detector is measured. Sophisticated electronics is required to measure these times accurately; in addition, a method of obtaining the start time is required. Ionization techniques capable of being pulsed are used, e.g. plasma desorption, laser desorption, atom/ion guns – these produce packets of ions with each pulse. Orthogonal instruments are now being developed which will allow the use of continuous ion sources such as electrospray (a simplified schematic is depicted in Figure 6). Traditionally, the resolution of time-of-flight analysers was considered to be low but modern instruments are capable of resolving powers up to 10 000. They have high transmission and are thus capable of high sensitivity; in addition they have a very high mass range. With the introduction of MALDI they have undergone a renaissance and continue to be developed. Commercial instruments interfaced to electrospray have recently been announced.

Figure 6 Schematic of a time-of-flight mass analyser with an orthogonal ESI source.

Instruments relying on ion cyclotron resonance (ICR) employ Fourier transform techniques and FT-ICR mass spectrometers are capable of achieving very high resolution. They require low pressures (\sim UHV) to operate effectively and the magnetic fields used are generated by super-conducting magnets. Ions, which may be formed directly within the ICR cell or injected from an external source (e.g. ESI, MALDI), are excited using a broad-band radiofrequency sweep and their cyclical motion induces an image current. This time domain signal is readily transformed to a mass spectrum by a Fourier transform. The very high resolution obtainable from this method of mass analysis enables separation of the isotopic peaks for each of the charge states resulting from ESI. This offers an advantage in the assignment of values of m and z in ESI mass spectra containing several masses.

Tandem Mass Spectrometry

Of the ionization techniques described, only the particle beam method produces sufficient fragmentation to give structural information. The softer ionization methods allow for RMM determination from either protonated molecule ions and/or adduct species, with little or no structural information being available owing to lack of fragmentation. It is possible to induce some degree of fragmentation in both thermospray and API sources by manipulating the source conditions. A more specific means of promoting fragmentation involves the use of sequential mass analysis, i.e. the isolation of a precursor ion followed by its interaction with a target gas to induce fragmentation by collisional activation, thus allowing a product ion mass spectrum to be recorded. This and other types of CID experiments can be carried out in time, in an ion storage device or in space using scanning or time-of-flight instruments. For a full discussion of the instruments and experiments possible, the reader is referred to the Further Reading section.

The most commonly used type of tandem mass spectrometer is the triple quadrupole, and benchtop instruments of this type with a dedicated LC interface are commercially available. They are relatively easy to use and offer a range of MS-MS scans. In addition to the product ion scan and the reaction monitoring scan (both MS1 and MS2 operate in selected ion mode), two other scan modes are available – precursor ion and constant neutral loss. In the former, MS1 is scanned whilst MS2 is set to pass a specific ion, thus yielding information as to the origins of a specific fragment ion. This may be employed to identify those components of a mixture which contain a common functional group, e.g. sulfonated compounds will typically fragment to give an ion at m/z 80 (SO_3^-) in negative ion mode; thus a precursor ion scan of this

ion should be specific for the presence of sulfonates. Neutral loss scans involve scanning both MS1 and MS2, but with the respective mass ranges offset by the mass of the neutral species.

Conclusion

This article has attempted to review the present situation with regards to the interfacing of LC to MS. LC-MS is now developing into a mature technique and modern instrumentation allows for routine and robust operation. Further developments will undoubtedly take place, with API and PB techniques to the forefront. The introduction of cheaper and easier-to-use benchtop instruments will promote continued expansion in the applications of this extremely powerful analytical method.

Detectors: Refractive Index Detectors

R. P. W. Scott, Avon, CT, USA

Copyright © 2000 Academic Press

Introduction

The refractive index detector is a bulk property detector. A bulk property detector responds to some physical property of the total column eluent and not some specific property of the solute. Bulk property detectors have an inherently limited sensitivity, irrespective of the instrumental technique used. Consider a hypothetical bulk property detector that is to monitor the density of the column eluent. Assume it is required to detect the concentration of a dense material, such as carbon tetrachloride (specific gravity 1.595), at a level of $1 \mu\text{g mL}^{-1}$ in *n*-heptane (specific gravity 0.684).

This situation will be particularly favourable for this hypothetical detector, as the solute to be sensed exhibits a large difference in density from that of the solvent. Let the change in density resulting from the presence of the solute at a concentration of 10^{-6}g mL^{-1} be Δd . It follows that, to a first approximation:

$$\Delta d = \frac{X_s(d_1 - d_2)}{d_1} \quad [1]$$

where d_1 is the density of the solute, carbon tetrachloride, d_2 is the density of the mobile phase, *n*-heptane, and X_s is the concentration of the solute to be detected.

Thus, for the example given:

$$\Delta d = \frac{(1.595 - 0.684) \times 10^{-6}}{1.59} = 5.71 \times 10^{-7} \quad [2]$$

Now the coefficient of cubical expansion of *n*-heptane is approximately 1.6×10^{-3} per $^{\circ}\text{C}$. Thus, the temperature, ΔT , that would produce a change in density equivalent to the presence of carbon tetrachloride at a concentration of 10^{-6}g mL^{-1} can be calculated.

It follows that:

$$\begin{aligned} \Delta T &= \frac{5.71 \times 10^{-7}}{1.6 \times 10^{-3}} ^{\circ}\text{C} \\ &= 3.6 \times 10^{-4} ^{\circ}\text{C} \end{aligned} \quad [3]$$

Assuming that a concentration of one part per million carbon tetrachloride is just detectable (it provides a signal-to-noise ratio of 2), then the temperature fluctuations must be maintained below $1.8 \times 10^{-4} ^{\circ}\text{C}$ to achieve this sensitivity. In practice, such temperature stability would be extremely difficult to maintain and thus the temperature control can severely limit the sensitivity obtainable from such a detector. Even the heat of adsorption and desorption of the solute to and from the stationary phase can easily result in temperature changes of this order of magnitude. The density of the contents of the cell will also change with pressure and, if there is a significant pressure drop across the cell, with flow rate. These restrictions apply to all bulk property detectors and so all bulk property detectors will have a limited sensitivity determined by the stability of the ambient conditions. This limit of detection is probably around 10^{-6}g mL^{-1} .

The refractive index detector was one of the first online detectors to be developed and was described by Tiselius and Claesson in 1942. It was also one of the first online liquid chromatography (LC) detectors to be made commercially for general use. The refractive index detector is probably the least sensitive of the commonly used LC detectors. Its major disadvantage (as already discussed) is its sensitivity to changes in ambient conditions, such as temperature, pressure and flow rate. Another handicap is that it cannot be used for gradient elution, due to the continuous change in mobile-phase refractive index that results from the change in solvent composition. Nevertheless, as the refractive index detector has a universal response, it can be extremely useful for detecting those compounds that are nonionic, do not absorb in the UV and do not fluoresce (e.g. aliphatic alcohols, fatty acids, ethers, etc.).

When a monochromatic ray of light passes from one isotropic medium, A, to another, B, it changes its velocity and direction. The change in direction is called the refraction, and the relationship between the angle of incidence and the angle of refraction is given by Snell's law:

$$n'_B = \frac{n_B}{n_A} = \frac{\sin(i)}{\sin(r)} \quad [4]$$

where i is the angle of incident light in medium A, r is the angle of refractive light in medium B, n_A is the refractive index of medium A, n_B is the refractive index of medium B and n'_B is the refractive index of medium B relative to that of medium A.

Refractive index is a dimensionless constant that normally decreases with increasing temperature; values given in the literature are usually quoted at 20°C or 25°C, the actual measurement taken as the mean value for the two sodium lines. If a cell takes the form of a hollow prism through which the mobile phase flows, a ray of light passing through the prism will be deviated from its original path. If the light is focused on to a photocell the output will change as the refractive index of the mobile phase in the cell changes. This method of monitoring refractive index is called the angle of deviation method and has been used by a number of manufacturers in their detector design.

The modern refractive index detector is the result of considerable research which has been extended by the research and development laboratories of many instrument companies. A diagram of a simple refractive index detector based on the angle of deviation method measurement is shown in **Figure 1**. A beam of light from an incandescent lamp passes through an optical mask that confines the beam to the region of the cell. The lens collimates the light beam, which passes through both the sample and reference cells to a plane mirror. The mirror reflects the beam back through the sample and reference cells to a lens, which focuses it on to a photocell.

The location of the beam, rather than its intensity, is determined by the angular deflection of the beam caused by the difference in refractive index between the contents of the two cells. As the beam changes its position of focus on the photoelectric cell, the output changes and the resulting difference signal is electronically modified to provide a signal proportional to the concentration of solute in the sample cell.

An alternative method of refractive index measurement, the Fresnel method, has also been used in the design of commercially fabricated detectors. The two different systems provide comparable performance with respect to sensitivity and linearity, and mostly differ in the manufacturing techniques used to construct the instruments. The relationship between the reflectance from an interface between two transparent media, and their respective refractive indices, is given by Fresnel's equation:

$$R = \frac{1}{2} \left[\frac{\sin^2(i - r)}{\sin^2(i + r)} + \frac{\tan^2(i - r)}{\tan^2(i + r)} \right] \quad [5]$$

where R is the ratio of the intensity of the reflected light to that of the incident light and the other symbols have the meanings previously assigned to them. Now:

$$\frac{\sin(i)}{\sin(r)} = \frac{n_1}{n_2} \quad [6]$$

where n_1 is the refractive index of medium 1 and n_2 is the refractive index of medium 2.

Consequently, if medium 2 represents the liquid eluted from the column, then any change in n_2 will result in a change in R and thus the measurement of R could determine changes in n_2 resulting from the presence of a solute. Conlon utilized this principle to develop a practical refractive index detector. His device, now obsolete, illustrates the principle of the Fresnel method very simply (**Figure 2**).

The sensing element consists of a rod prism sealed into a tube through which the solvent flows. The rod prism is made from a glass rod 6.8 mm in diameter

Figure 1 The refractive index detector based on the angle of deviation method of measurement. (Courtesy of Waters Chromatography.)

Figure 2 Early detector based on the Fresnel method of refractive index measurement.

and 10 cm long, bent to the correct optical angle (just a little less than the critical angle) and an optical flat is ground on the apex of the bend, as shown in Figure 2. The optical flat is then sealed into the window of a suitable tube that acts as a flow-through cell. The photocell is arranged to be one arm of a Wheatstone bridge and a reference photocell (not shown) monitoring light direct from the cell is situated in another arm of the bridge.

This detector was never manufactured as it had too large a cell volume and limited sensitivity. However, it was one of the first refractive index detectors to work on the Fresnel principle. A commercial refractive index detector that works on this principle is shown in Figure 3.

Light from a tungsten lamp is directed, through an infrared filter to prevent heating the cell, to a magnifying assembly that also splits the beam into two. The two beams are focused through the sample and reference cells respectively. Light refracted from the mobile phase/prism surface passes through the prism assembly and is then focused on two photocells. The

prism assembly also reflects light to a user port where the surface of the prism can be observed. The output from the two photocells is electronically processed and either passed to a potentiometric recorder or a computer data acquisition system.

The range of refractive index covered by the instrument for a given prism is limited and consequently three different prisms are made available to cover the refractive index ranges of 1.35–1.4, 1.41–1.44 and 1.40–1.55 respectively. An example of the separation of a series of polystyrene standards monitored by the detector is shown in Figure 4. The separation was carried out by size exclusion on a column packed with 5 μm particles operated at a flow rate of 0.8 mL min^{-1} .

The Christiansen Effect Detector

This method of measuring refractive index arose from the work of Christiansen on crystal filters. If a cell is packed with particulate material having the same refractive index as the mobile phase passing through it, light will be transmitted through the cell with little or no refraction or scattering. If, however, the refractive index of the mobile phase changes, there will be a refractive index difference between the mobile phase and that of the packing. This difference will result in light being refracted away from the incident beam and thus reduce the intensity of the transmitted light. If the transmitted light is focused on to a photocell, and the refractive index of the packing and mobile phase initially matched, then any change in refractive index resulting from the elution of a solute peak will cause light scattering. This scattering will reduce the intensity of the light falling on the sample photocell and thus provide a differential output relative to that of the reference cell.

Figure 3 Diagram of the optical system of a refractive index detector operating on the Fresnel principle. (Courtesy of Perkin Elmer.)

Figure 4 Separation of some polystyrene standards using a refractive index detector operating on the Fresnel principle. (Courtesy of Perkin Elmer.)

As the optical dispersions of the media are likely to differ, the refractive indices of the packing and the solvent will only match at one particular wavelength. Consequently, the fully transmitted light will be largely monochromatic. Light of other wavelengths will be proportionally dispersed depending on their difference from the wavelength at which the two media have the same optical dispersion. It follows that a change in refractive index of the mobile phase will change both the intensity of the transmitted light and its wavelength content.

A Christiansen detector is shown in **Figure 5**. The optical module contains a prefocused lamp, the voltage of which is adjustable to allow operation at low energy when the maximum sensitivity is not required. The condensing lens, aperture, achromat and beam-splitting prisms are mounted in a single tube to prevent contamination from dust and permit easy optical alignment. The system has two identical and interchangeable cells. The disadvantage of this detector is that the cells must be changed when alternative mobile phases are used in order to have a packing with

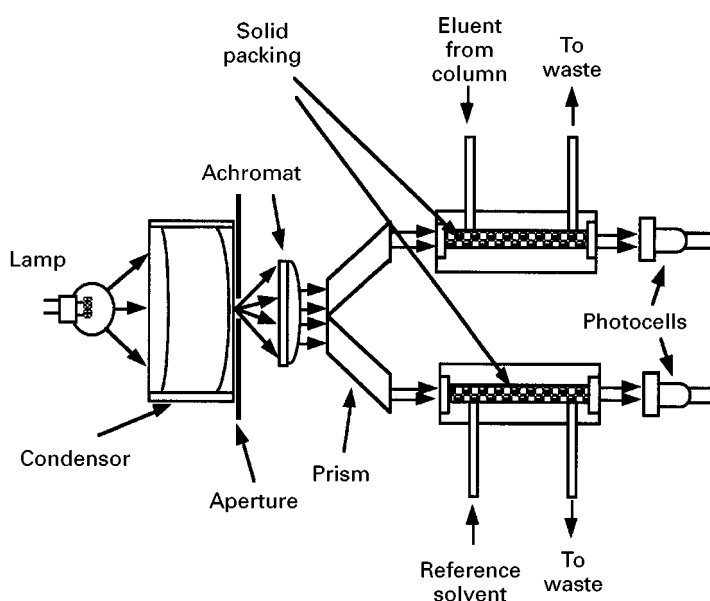

Figure 5 The Christiansen effect detector.

the appropriate refractive index. Close matching of the refractive indices of the cell packing and the mobile phase can be achieved by using mixed solvents.

Solvent mixing can usually be achieved without significantly affecting the chromatography distribution system, e.g. a small proportion of *n*-heptane in a mixture can be replaced with either *n*-hexane or *n*-octane either to increase or decrease the refractive index. The limitations inherent in this type of refractive index measurement, taken in combination with general disadvantages of the refractive index detector *per se*, have prevented this detector becoming very popular. This device has been claimed to have a sensitivity of 1×10^{-6} refractive index (RI) units. This would be equivalent to a sensitivity of 9×10^{-6} g mL⁻¹ of benzene (RI = 1.501) eluted in *n*-heptane (RI = 1.388). The cell was designed to have a minimum volume of 8 μ L, which is slightly large for modern sensors, but small enough to work well with normal 4.6 mm i.d. columns. Different cells packed with appropriate materials were necessary to cover the refractive index range of 1.31–1.60.

The Interferometer Detector

The interferometer detector was first developed by Bakken and Stenberg in 1971. The detector responds to the change in the effective path length of a beam of light passing through a cell, when the refractive index of its contents changes, due to the presence of an eluted solute. If the light transmitted through the cell is focused on a photocell coincident with a reference beam of light from the same source, interference fringes will be produced. These fringes will change, as the pathlength of one light beam changes with reference to the other. Consequently, as the concentration of solute increases in the sensor cell, a series of electrical pulses will be generated as each fringe passes the photocell.

The effective optical path length (d) depends on the change in refractive index (Δn), and the path length (l) of the sensor cell:

$$d = \Delta n l \quad [7]$$

It is possible to calculate the number of fringes (N : sensitivity) which move past a given point (or the number of cyclic changes of the central portion of the fringe pattern) in relation to the change in refractive index by the equation:

$$N = \frac{2\Delta n l}{\lambda} \quad [8]$$

where λ is the wavelength of the light employed.

As N increases for a given refractive index change, Δn , so will the detector sensitivity. Therefore l should be made as large as possible commensurate with the chromatographic properties of the system. The simple optical system originally employed by Bakken and Stenberg is shown in Figure 6. Light from a source strikes a half-silvered mirror and is divided into two paths. Part of the beam is reflected by a plane mirror back along the same path and on to a photocell. The other part of the beam passes through the sensor cell to a plane mirror, where it is reflected back again through the sensor cell to the half-silvered mirror that reflects it on to the photocell where interference takes place with the other half of the light beam.

The number of fringes that pass the sensor will be directly proportional to the total change in refractive index, which will be proportional to the total amount of solute present. Although it establishes the technical viability of the system, the apparatus has limited use, but it has been developed into a practical instrument and an example is that developed by Wyatt Technology. The optical system of the Optilab interference detector is shown in Figure 7.

Light from an appropriate source is linearly polarized at -45° to the horizontal plane. Horizontal and vertical polarized light beams are produced and, on passing through the Wollaston prism, one passes through the sample cell and the other through the reference cell. The beam passing through the sample cell is horizontally polarized and that through the reference cell is vertically polarized. After passing through the cells, the beams are focused on a second Wollaston prism and then through a quarter-wave plate which has its fast axis set -45° to the horizontal plane.

A beam that is linearly polarized in the fast-axis plane will, after passing through the plate, lead another linearly polarized, but orthogonal, beam by a quarter of a wavelength. The phase difference results in a circularly polarized beam. It can be assumed that each of the beams focused on the Wollaston prism consists of two such perpendicular beams which, after the quarter-wave plate, result in two circularly polarized beams of opposite rotation. These beams will interfere with each other to yield the original linearly polarized beam. A second polarizer is placed at an angle $(90 - \beta)$ to the first (for the significance of β , see below), allowing about 35% of the signal to reach the photocell. A filter-transmitting light at 546 nm precedes the photocell.

If the sample cell contains a higher concentration of solute than the reference cell, in general the refractive index will be higher and the interfering beams will be out of phase. The refractive index difference (Δn) and

Figure 6 The original optical system used by Bakken and Stenberg in their interferometer detector.

the phase difference (Δp) are related by:

$$\Delta p = \frac{2\pi L \Delta n}{\lambda} \quad [9]$$

$\Delta p/2$ rad, and the amplitude of the light striking the photocell (A_p) will be given by:

$$A_p = A_0 \cos\left(90 - \beta - \frac{\Delta p}{2}\right) = A_0 \cos\left(\beta - \frac{\Delta p}{2}\right) \quad [10]$$

where L is the length of the cell and λ is the wavelength of the light.

The circularly polarized beams will interfere to yield a linearly polarized beam which is rotated

The smallest cell (1.4 μL : a cell volume that would be suitable for use with microbore columns) is re-

Figure 7 The Optilab interference refractometer detector.

Figure 8 The layout of a thermal lens detector.

ported to give a sensitivity of about 2×10^{-7} RI units at a signal-to-noise ratio of 2. Consequently, for benzene (RI = 1.501) sensed as a solute in *n*-heptane (RI = 1.388), this sensitivity represents a minimum detectable concentration of $5.6 \times 10^{-5} \text{ g mL}^{-1}$. The alternative $7 \mu\text{L}$ cell would decrease the minimum detectable concentration to about $1 \times 10^{-6} \text{ g mL}^{-1}$, similar to that obtained for other refractive index detectors. However, this cell volume is slightly large for modern high efficiency columns.

The Thermal Lens Detector

There are a number of detectors that have been developed that are not classed as refractive index detectors, but their response is either based directly on refractive index measurement, or a function of some physical property of the mobile-phase system that is related to the refractive index. One such example of these is the thermal lens detector.

When a laser is focused on to an absorbing substance, the refractive index may be changed and modify the medium in such a way that it behaves as a lens. This phenomenon was first reported by Gorden *et al.* in 1964 and subsequently the effect has been examined by a number of workers. The formation of the thermal lens is caused by the absorption of laser light which may be extremely weak. The excited-state molecules subsequently decay to the ground state, with a resulting localized temperature increase in the sample. As the refractive index of the medium depends on the temperature, the spatial variation of the refractive index in the medium produces the phenomenon which appears to be equivalent to the formation of a lens within the medium. The temperature coefficient of refractive index is, for most liquids, negative; consequently, the insertion of a liquid in the laser beam produces a concave lens that results in beam divergence. The thermal lens effect has been used

by Buffet and Momis to develop a small volume detector. Their system is shown in **Figure 8**.

The device consists of a heating laser, from which light is passed directly through the sample via two lenses and a half mirror. Another laser, the probe laser, passes light in the opposite direction, through one lens, then through the sample to the half mirror where the light is reflected on to a photocell. Between the mirror and the photocell is a filter to remove the heating laser light and a small pinhole aperture. When an absorbing solute arrives in the cell, a thermal lens is produced which causes the probe light to diverge, and consequently the intensity of the light passing through the pinhole and on to the photocell is reduced. The cell can be made a few microlitres in volume and would thus be suitable for use with microbore columns. A sensitivity of 10^{-6} AU (the expected limiting sensitivity of a bulk property detector) was claimed for the detector and a linear dynamic range of about three orders of magnitude.

The use of two lasers adds significantly to the cost of the device. Basically, the thermal lens detector is a special form of the refractive index detector and as a consequence can be considered as a type of universal detector. However, it cannot be used with gradient elution or flow programming and its sensitivity is no better than other refractive index detectors.

Conclusion

Despite the refractive index detector being the oldest and least sensitive of all the LC detectors, its use survives, and will continue to survive, due to its universal response. All other LC detectors that are in use have sensors that only respond to certain types of solutes and therefore are restricted to specific sample types. At any time a new type of cathodic detecting system might be devised, but

after 30 years of detector development, only the evaporative light-scattering detector has offered any viable alternative. As a consequence, the future of the refractive index detector for specific applications still appears assured. In most applications an isocratic development procedure can be found that will provide satisfactory resolution of those solutes of interest, and so the problem of gradient elution can be circumvented. In addition, by using columns of 4.6 mm i.d. or more, the limited sensitivity of the refractive index detector can also be accommodated.

Detectors: UV/Visible Detection

R. P. W. Scott, Avon, CT, USA

Copyright © 2000 Academic Press

The UV absorption detector, introduced in the early 1960s, was the first high sensitivity liquid chromatography detector to be developed. UV absorption detectors are considered to be those detectors that can sense substances that absorb light over the wavelength range 180–350 nm. Many compounds absorb light in this range, including those substances having one or more double bonds (π electrons) and those that have unshared (unbonded) electrons, e.g. all olefins, all aromatics and compounds, for example, containing $>C=O$, $>C=S$ and $-N=N-$ groups. As a result, providing the wavelength of the incident light can be selected, the UV detector tends to perform as a universal detector. There are exceptions: the UV detector will not readily detect hydrocarbons, aliphatic alcohols or other substances that do not have a UV chromophore that will absorb light in the wavelength range already defined.

The sensor cell consists of a short cylindrical tube having two terminating flat quartz windows and radial connections at either end for the column eluent to enter and to leave. To reduce band dispersion, the volume of the cell is usually limited to between 2 and 5 μ L. The UV light passes axially through the end windows and falls on a photoelectric cell (or array), the output from which is conveyed to an appropriate amplifier and thence to a recorder or data acquisition system.

The cell must be carefully designed to reduce peak dispersion that would result from the natural parabolic velocity profile of the mobile phase as it passes through the cell. A diagram of a typical UV absorption sensor cell is shown in Figure 1. The inlet and outlet conduits are designed to produce secondary flow and break up the parabolic velocity profile that

causes peak dispersion. Mobile phase enters the cell at an angle, and is directed at the cell window. As a consequence, the stream of mobile phase must virtually reverse its direction to pass through the cell, producing a strong radial flow which disrupts the Newtonian flow.

The same situation is arranged to occur at the exit end of the cell. The flow along the axis of the cell must reverse its direction to pass out of the port that is set at an angle to accomplish the same effect. By employing this type of cell geometry, dispersion in the cell resulting from viscous flow can be practically eliminated.

Figure 1 A simple UV detector sensor cell.

The relationship between the intensity of UV light transmitted through a cell (I_T) and the concentration of solute in it (c) is given by Beer's law:

$$I_T = I_0 e^{-\epsilon l c} \quad \text{or} \quad \ln(I_T) = \ln(I_0) - \epsilon c l \quad [1]$$

where I_0 is the intensity of the light entering the cell, l is the path length of the cell, and ϵ is the molar extinction coefficient of the solute for the specific wavelength of the UV light.

If eqn [1] is put in the form:

$$I_T = I_0 10^{-\epsilon l c} \quad [2]$$

The sensitivity of the detector is directly proportional to the value of the absorption coefficient and the path length of the cell. Thus, the sensitivity of the detector can be increased by increasing the path length. However, the volume of the cell must also be constrained to avoid more than a small fraction of a peak existing in the cell at any one time (this can cause peak dispersion and, at the extreme, when two peaks exist in the tube, peak merging). Consequently, as the length is increased, the radius must be reduced, which will increase the detector noise and cause a reduction in sensitivity. Thus, increasing the detector sensitivity by increasing the path length has limitations, and a well-designed cell involves a careful compromise between cell radius and length to provide the maximum sensitivity. Most modern UV detector sensors have path lengths that range between 1 and 10 mm and internal radii that range from about 0.25 to 1 mm.

From eqn [2]:

$$\log \frac{I_T}{I_0} = \epsilon l c = A \quad [3]$$

where A is termed the absorbance.

The term ΔA is often employed to define the detector sensitivity where the value of ΔA is the change in absorbance that provides a signal-to-noise ratio of 2, i.e.:

$$\Delta A = \epsilon l \Delta c \quad [4]$$

where (Δc) is the detector concentration sensitivity or minimum detectable concentration. Thus:

$$\Delta c = \frac{\Delta A}{l \epsilon} \quad [5]$$

It is clear that two detectors having the same sensitivity, defined as ΔA , will not necessarily have the same sensitivity with respect to solute concentration.

Two detectors having the same minimum detectable change in absorbance will only exhibit the same concentration sensitivity if the path lengths of the two sensors are identical.

UV detectors can be used with gradient elution providing the solvents do not absorb significantly over the wavelength range that is being used for detection. The solvents employed in reversed-phase chromatography are usually water, methanol, acetonitrile and tetrahydrofuran (THF), all of which are transparent to UV light over the wavelength range commonly used. In normal-phase operation, however, more care must be taken in solvent selection, as many solvents that would be appropriate for the separation absorb UV light very strongly. The *n*-paraffins, dichloromethane, and *n*-paraffins containing small quantities of aliphatic alcohols or THF are useful solvents that are transparent in UV, and can be used with normal distribution systems (e.g. with a polar stationary phase such as silica gel).

There are two types of UV detector: fixed-wavelength detector and multiple-wavelength detector.

Fixed-wavelength Detector

The fixed-wavelength detector functions with light of a single wavelength (or nearly so) generated by a specific type of discharge lamp. The most popular lamp for this purpose is the low pressure mercury vapour lamp, which generates most of its light at 254 nm. There are other lamps that are used with fixed-wavelength UV detectors: the low pressure cadmium lamp which generates light predominantly at 225 nm and the low pressure zinc lamp that emits light at 214 nm. None of the lamps are monochromatic and light of other wavelengths is always present but usually at a significantly lower intensity. The low pressure mercury light source (actual maximum emission wavelength 253.7 nm) is the lamp which is most frequently used in the fixed-wavelength detector.

The typical optical system of a fixed-wavelength UV detector is shown in **Figure 2**. Light from the UV source is collimated by a suitable lens through the sample cell and the reference cell, and then on to two photocells. The cells are cylindrical, with quartz windows at either end. The reference cell compensates for any absorption that the mobile phase might have at the sensing wavelength. The outputs from the two photocells are passed to a signal-modifying amplifier so that the output is linearly related to the concentration of solute being detected.

For reasons already discussed, modern sensor cells have angular conduits that form a Z shape to reduce dispersion. The UV detector can be fairly sensitive

Figure 2 A fixed-wavelength UV detector.

to both flow rate and pressure changes but this instability can be greatly reduced if the sensor is well thermostatted. The fixed wavelength UV detector was once one of the most commonly used LC detectors; it is sensitive, linear and relatively inexpensive. However, today the diode array detector is the most popular, despite its much higher price. The sensitivity (minimum detectable concentration) of the fixed-wavelength detector to compounds with favourable detection properties is about $5 \times 10^{-8} \text{ g mL}^{-1}$, with a linear dynamic range of about three orders of magnitude.

Multiple-wavelength Detector

The multiple-wavelength detector requires a source that emits light over a wide range of wavelengths and, with the aid of a monochromator, light of a specific wavelength can be selected for detection purposes. Detector sensitivity can be improved by selecting light of a wavelength at which the solute has its maximum absorption. Alternatively, the emerging solution peak can be scanned over a range of wavelengths, and the absorption spectra of eluted substances can be used for identification purposes.

There are two basic types of multiple-wavelength detector: the dispersion detector and the diode array detector, the latter being the more popular. In fact, there are currently very few dispersion instruments commercially available but as there are many still in use, their characteristics will be discussed.

The two types of multiple-wavelength detectors have important differences. In the dispersive instrument, the light is dispersed before it enters the sensor cell, and thus virtually monochromatic light passes

through the cell. However, if the incident light can excite the solute and cause fluorescence at another wavelength, then the light falling on the photocell will contain that incident light that has been transmitted through the cell, together with any fluorescent light that may have been generated in the cell. Consequently, the light monitored by the photocell will not be solely monochromatic and light of another wavelength, if present, could impair the linear nature of the response. In most cases this effect is negligible, but with some substances it may be quite significant. The diode array detector operates in quite a different manner. Light of all wavelengths generated by the deuterium lamp is transmitted through the cell, and the transmitted light is then dispersed over an array of diodes. In this way, absorption at discrete groups of wavelengths is continuously monitored at each diode. However, the light falling on a discrete diode may not be solely that transmitted through the cell from the source, but may contain fluorescence light excited by light of a shorter wavelength. In this case, the situation is exacerbated by the fact that the cell contents are exposed to all the light emitted from the lamp, and so fluorescence is more likely. In general, this means that, under some circumstances, the transmitted light measured may also contain fluorescent light. As a consequence, the absorption spectrum obtained for a given substance may be degraded from the true absorption curve.

The ideal multiple-wavelength detector would be a combination of both the dispersion instrument and the diode array detector. This system would allow a monochromatic light beam to pass through the detector and then the transmitted beam would itself be dispersed again on to a diode array. Only that diode corresponding to the wavelength of the incident light would be used for monitoring the transmission. In this way any fluorescent light would strike other diodes, the true absorption would be measured and, if the incident light is scanned, accurate absorption spectra could be obtained.

The Multiple-wavelength Dispersive UV Detector

A conventional multiple-wavelength dispersive UV detector is shown in **Figure 3**. Light from the source is collimated by two curved mirrors on to a holographic diffraction grating. The dispersed light is then focused by means of a curved mirror on to a plane mirror and light of a specific wavelength is selected by appropriately positioning the angle of the plane mirror. Light of the selected wavelength is then focused by means of a lens through the flow cell and, consequently, through the column eluent. The exit beam from the cell is then focused by another lens on to a photocell which gives a response that is some func-

Figure 3 The multiple-wavelength dispersive UV detector. Courtesy of the Perkin Elmer Corporation.

tion of the intensity of the transmitted light. The detector is usually fitted with a scanning facility that, by arresting the flow of mobile phase, allows the spectrum of the solute contained in the cell to be obtained. Due to the limited information given by most UV spectra, and the similarity between UV spectra of widely different types of compounds, the UV spectrum is not usually very reliable for structure elucidation.

UV spectra are, however, useful for determining the homogeneity of a peak by obtaining spectra from a sample on both sides of the peak. The technique is to normalize both spectra, then either subtract one from the other and show that the difference is close to zero, or take the intensity ratio across the peak and show that it is constant throughout the peak.

A common use of the multiple-wavelength detector is to select a wavelength that is characteristically absorbed by a particular component or components of a mixture to enhance the sensitivity of the detector to those particular solutes. Alternatively, by choosing a characteristic absorption wavelength of the solute, the detector response can be made specific to the solute(s) and thus not respond significantly to other substances in the mixture that are of little interest.

The early multiple-wavelength, dispersive UV detector proved extremely useful, providing adequate sensitivity, versatility and a linear response. It was found, however, to be bulky (due to the need for a relatively large internal optical bench), required mechanically operated wavelength selection and a stop/flow procedure to obtain spectra 'on-the-fly'. The alternative diode array detector has all the ad-

vantages but none of the disadvantages and, as a result, has become the variable-wavelength UV detector of choice.

The Diode Array Detector

The diode array detector also utilizes a deuterium or xenon lamp that emits light over the UV spectrum range. Light from the lamp is focused by means of an achromatic lens through the sample cell and on to a holographic grating. The dispersed light from the grating is arranged to fall on a linear diode array.

The resolution of the detector ($\Delta\lambda$) will depend on the number of diodes (n) in the array, and also on the range of wavelengths covered ($\lambda_2 - \lambda_1$). Thus:

$$\Delta\lambda = \frac{\lambda_2 - \lambda_1}{n} \quad [6]$$

It is seen that the ultimate resolving power of the diode array detector will depend on the semiconductor manufacturer and on how narrow the individual photocells can be commercially fabricated.

A diode array detector is shown in **Figure 4**. Light from the broad emission source is collimated by an achromatic lens, so that the total light passes through the detector cell on to a holographic grating. In this way the sample is subjected to light of all wavelengths generated by the lamp. The dispersed light from the grating is then allowed to fall on to a diode array. The array may contain many hundreds of diodes, and the output from each diode is regularly sampled by a computer and stored on a hard disk. At the end of

Figure 4 The diode array detector.

Figure 5 Dual-channel plot from a diode array detector confirming peak purity. Chlorthalidone was isolated from a sample of tablets and separated by a reversed-phase (C_{18}) column 4.6 mm i.d., 3.3 cm long, using a solvent mixture consisting of 35% methanol, 65% aqueous acetic acid solution (water containing 1% acetic acid). Flow rate: 2 mL min^{-1} . Courtesy of the Perkin Elmer Corporation.

the run, the output from any diode can be selected and a chromatogram produced using the UV wavelength that was falling on that particular diode.

Most instruments will allow at least one diode to be monitored in real time, so that a chromatogram can be generated as the separation develops. This system is ideal, as by noting the time of a particular peak, a spectrum of the solute can be obtained by recalling from memory the output of all the diodes at that particular time. This directly produces the spectrum of the solute. The diode array detector can be used in a number of unique ways: one example is to use it to verify the purity of a given solute, as shown in Figure 5. The chromatogram, monitored at 274 nm, is shown in the lower part of Figure 5. As a diode array detector was employed, it was possible to ratio the output from the detector at different wavelengths and plot the ratio simultaneously with the chromatogram monitored at 274 nm. Now, if the peak were pure and homogeneous, the ratio of the absorption at the two wavelengths (those selected being 225 and 245 nm) would remain constant throughout the elution of the entire peak.

The top part of Figure 5 shows this ratio plotted on the same time scale as the elution curve, and it is seen

Figure 6 Separation of some aromatic hydrocarbons. Separation was carried out on a 3 cm long, 4.6 mm in diameter column packed with a $3 \mu\text{m}$ C_{18} sorbent. Courtesy of the Perkin Elmer Corporation.

that a clean rectangular peak is produced, confirming a constant absorption ratio at the two wavelengths. The wavelengths chosen to provide the confirming ratio will depend on the UV absorption characteristics of the substance concerned. Another interesting example of the use of the diode array detector to confirm the integrity of an eluted peak is afforded by the separation of the series of aromatic hydrocarbons shown in Figure 6.

It is seen that the separation appears to be satisfactory and, without further evidence, it would be reasonable to assume that all the peaks were pure. However, by plotting the absorption ratio, 250 nm/255 nm, for the anthracene peak it becomes evident that the tail of the peak contains an impurity as the clean rectangular shape of the ratio peak is not realized. The absorption ratio peaks are shown in Figure 7.

The presence of an impurity is confirmed unambiguously by the difference in the spectra obtained for

Figure 7 Curves relating the absorption ratio and elution time.

Figure 8 Superimposed spectra taken at the leading and trailing edges of the anthracene peak.

the leading and trailing edges of the peak. Spectra taken at the leading and trailing edge of the anthracene peak are shown superimposed in **Figure 8**. Further work identified the impurity to be 5% *t*-butylbenzene.

The diode array detector is now generally considered the most versatile and useful detector for everyday use in liquid chromatographic analyses. The performances of both types of multiple-wavelength detectors are very similar and typically have a sensitivity of about $1 \times 10^{-7} \text{ g mL}^{-1}$ and a linear dynamic range of about three orders of magnitude: 1×10^{-7} to $5 \times 10^{-4} \text{ g mL}^{-1}$. The device automatically records a spectrum at each sampling point and thus is extremely rapid. It is very suitable for use with fast separations completed in a few seconds.

The use of UV detection in capillary electrochromatography and for detection in capillary electrophoresis has enjoined a novel cell design. As the peaks are only a few nanolitres in volume, the sensor volume must be commensurately small. A practical detector has been constructed by removing the polyimide coating from the surface of a short length of quartz capillary tubing, as shown in **Figure 9**.

UV light from a suitable lamp traverses the tube window and falls on to a photocell. As the solutes migrate across the window they are detected by light absorption in the usual manner. Considering the expression given in eqn [1] for the output of the detector, it appears that, due to the very short pathlength of the cell (*c.* 300 μm), the detector would be very insensitive. However, the loss of sensitivity caused by the reduced pathlength is partly compensated by the relatively high solute concentration in the peaks resulting from the very high column efficiencies achieved in capillary electrochromatography (*c.* 10^5 theoretical plates). The electronic circuitry used with

Figure 9 UV detector cell for capillary electrochromatography.

the microcell is basically the same as that used in the conventional larger cell detectors.

Conclusion

The design of the UV detector has changed little over the last decade and its performance has been only marginally improved. Radical changes do not appear likely in the future, although slow progress in improved sensitivity and cell design can be anticipated. The diode array detector is likely to continue as the 'workhorse' detector for liquid chromatography for many years to come. Further details on liquid chromatography detector design and performance can be found in the Further Reading section.

Electrochemically Modulated Liquid Chromatography

Introduction

Liquid chromatographic separations rely on subtle differences in the interactions of analytes between a mobile phase and a stationary phase. Examples include the separation of charged species using ion-exchange chromatography, enantiomeric compounds via chiral selective chromatography, and polymeric materials by size-exclusion chromatography. Each of these separations, however, requires a different stationary phase. Thus, a large number of such phases and mobile phase elution schemes are required to tackle the diversity of the separations routinely encountered in the analytical laboratory.

Recently, a technique has been developed that begins to address the need for a large number of stationary phases. The approach, which is termed 'electrochemically modulated liquid chromatography' (EMLC), is based on the transformation of a conductive stationary phase in a conventional liquid chromatographic system into the working electrode of a three-electrode electrochemical cell. With this arrangement, the column packing serves both as a stationary phase and as a working electrode. This dual-purpose function provides the ability to induce changes in the interfacial properties (e.g. donor-acceptor strength, solvophobicity, and oxidation state) of conductive stationary phases through alterations in applied potential which subsequently translate into changes in analyte retention. The column can therefore be viewed as a compositionally tunable stationary phase with retention characteristics that can be manipulated both prior to as well as during elution by changes in applied potential. The latter capability presents an approach whereby improvements in a separation can be realized through a dynamic alteration in the composition of a stationary phase that is conceptually, but not mechanistically, analogous to conventional solvent gradient elution techniques in liquid chromatography or to temperature-programming strategies in gas chromatography. With electrochemically modulated liquid chromatography, however, the changes in retention reflect a temporal gradient in the composition of a stationary phase.

The following discusses the emergence of this new separation strategy as a tool in the arsenal of liquid chromatography techniques. After examining issues

concerning the design and construction of the column, processes to control retention, illustrative applications demonstrating the versatility of the technique and issues related to improvements in column performance are presented.

Hardware

Column Development

The development of electrochemically modulated liquid chromatography can be traced back to the early 1950s and 1960s when concepts for the desalination of water and for the separation of metal ions explored a union of liquid chromatographic and electrochemical techniques. These and many subsequent investigations suffered from poor chromatographic efficiency ($10\text{--}200$ plates m^{-1}). As a consequence, interest in this technique has been limited until a few years ago. This limitation reflected the complexity in merging the design criteria necessary for both effective liquid chromatographic and electrochemical performance. In the case of the latter, a column must incorporate a reference electrode as a means to control precisely the potential applied to the stationary phase, and an auxiliary electrode as a means to complete the electrical circuit for current flow. In addition, the components of the column must be electrochemically as well as chemically inert and the mobile phase may need to be modified by the addition of an inert electrolyte to achieve the necessary solution conductivity; this modification is required to minimize the solution resistance of the mobile phase which, if not effectively manipulated, may degrade the ability to control the potential applied to the stationary phase.

Maintaining control over the applied potential is challenged, however, by the need for conductive stationary phases that have the characteristic size, shape, and surface area (e.g., $200\text{ m}^2\text{ g}^{-1}$) required for high separation efficiencies with packed columns. A critical design attribute for high performance chromatography is a large surface area to solution volume ratio for the stationary phase with respect to the mobile phase. As a consequence, the small voids between the particles and within the pores of the particles that often make up a stationary phase appear as highly resistive pathways in an equivalent electrical circuit model for a column under potential control. These high-resistance networks define the time required to charge the electrical double layer at the surface of the stationary phase, and therefore the

flow generated at the high surface area working electrode and as an inflexible container that defines the length and diameter of the column. The electrical circuit is completed by placing a reference electrode (e.g. Ag/AgCl(saturated NaCl)) inside a glass reservoir that surrounds the porous stainless-steel tubing and is filled with an aqueous electrolyte.

The ion-exchange membrane has three important functions in this design. It serves as:

- an insulating container that separates the stationary phase from the stainless-steel auxiliary electrode;
- an ionic bridge that completes the electrical connection between the stationary phase and auxiliary electrode; and
- a barrier that minimizes the loss of analyte through the porous stainless-steel cylinder as well as the possible contamination of the column by any electrolysis products generated at the auxiliary electrode.

With this design, the column equilibrates to alterations in applied potential on a time scale similar to that required for changes in mobile phase (~ 20 min), and performs at high chromatographic efficiencies (e.g., $15\,000$ plates m^{-1}).

Stationary Phases

Several types of conductive materials have been tested for use as packings in electrochemically modulated liquid chromatography. Some of the earlier examples investigated the utility of silver grains, mercury-coated platinum, uncoated graphitic particles, and various organic materials (e.g., conductive polymers) coated on graphitic particles. In general, the stationary phase material must meet the requirements in place for conventional liquid chromatography. These attributes include chemical inertness, high mechanical strength, high surface area, and small uniform size. To be effective as an electrode material, requirements including reasonable electrical conductivity ($\geq 0.01 \Omega\text{-cm}$) and stability over a wide range of applied voltage must be added to the list of attributes. For packings designed to undergo a formal change in oxidation state through an externally triggered electron-transfer process, the material must also be stable in both its oxidized and reduced forms.

Of the above materials, the greatest degree of success has been achieved to date using uncoated carbonaceous materials such as nonporous glassy carbon and porous graphitic carbon. These materials are stable both chemically (i.e. can be used in strongly

acidic and basic mobile phases) and electrochemically (i.e. can be used over a wide range of applied potentials), have a high mechanical strength, and are commercially available as micron-sized particles. The non-porous material, has a lower surface area ($\sim 1 \text{ m}^2 \text{ g}^{-1}$) and therefore a lower separation efficiency, whereas the porous material has a higher surface area ($\sim 200 \text{ m}^2 \text{ g}^{-1}$) and therefore a higher separation efficiency. The coated materials, especially those that undergo a formal change in oxidation state (see below), potentially offer an additional dimension in affecting a separation, but complications regarding stability and reliable coating procedures remain significant issues.

Ancillary Instrumentation

Other than the features described for the column, this technique uses standard analytical laboratory hardware. Commercially available liquid chromatographic systems (e.g. pump, injector, and detector) and electrochemical hardware (e.g. potentiostat) are all that are needed to perform separation using electrochemically modulated liquid chromatography. To minimize the time required to re-equilibrate the column to changes, the use of a potentiostat with a high output power (i.e. a few watts) is recommended.

Retention Concepts

Conventional liquid chromatographic separations rely on a partitioning of an analyte between a mobile phase and stationary phase. This equilibrium is generally expressed as a distribution coefficient (K_d) where:

$$K_d = C_s/C_m \quad [1]$$

and C_s and C_m are the concentrations of an analyte in the stationary and mobile phases, respectively. Electrochemically modulated liquid chromatography therefore relies on the impact of the applied potential on the retention of an analyte through alterations in K_d .

Four principal formats have been used. The first format deals with an electrochemically induced reduction of metal ions (M^{n+}) onto a conductive stationary phase as M^0 . The generic form of this reaction can be written as:

where n represents the electron (e^-) stoichiometry of the reaction. The concentrations of the two species are then defined by the difference in the

standard reduction potential for the reaction (E^0) and the applied potential (E_{app}) through the Nernst equation:

$$E_{\text{app}} = E^0 + (0.059/n)(\log[M^0]/[M^{n+}]) \quad [3]$$

Substituting M^0 and M^{n+} into eqn [1] for C_s and C_m , respectively, and then combining eqns [1] and [3] yields:

$$\log K_d = (n/0.059)(E^0 - E_{\text{app}}) \quad [4]$$

Eqn [4] shows that K_d changes by a factor of ten for every $0.059/n$ V alteration of the applied potential. However, while providing a means for the quantitative deposition of metal ions, the process suffers from poor selectivity. That is, metal ions with standard reduction potentials more positive than the applied potential are exhaustively deposited onto the column, whereas those with standard reduction potentials more negative than the applied potential pass through the column without being retained. Strategies that have been devised to address this limitation have been studied in a few specific applications.

The second format takes a notably different tactic in that the potential applied to a graphitic stationary phase is used to manipulate the chemical composition of a mobile phase. This strategy relies on the oxidation or reduction of water either to increase or decrease, respectively, the acidity of the mobile phase. This general tactic, though explored only briefly to manipulate the pH-dependent binding of metal ions to chelates immobilized onto the column packing, will undoubtedly be more extensively

exploited as interest in this new separation technique increases.

The third format, which has been the most used of the four, utilizes uncoated graphitic stationary phases. The basis of this format derives largely from the effect of the applied potential on the donor-acceptor properties (e.g. electrostatic and dipolar interactions) of the packing and is illustrated in Figure 2. Thus, as the applied potential becomes more positive, the carbonaceous packing becomes a stronger acceptor and analytes with a predominant donor character are more strongly retained. The retention of analytes with a predominant acceptor character, in contrast, increases as the applied potential becomes more negative. This approach has been employed, as discussed in the following section, to separate a wide ranges of samples, including, charged and neutral aromatic compounds, important pharmaceutical agents, and enantiomeric pairs.

The fourth format takes advantage of a different form of electrochemically modulated separation in which the composition of a column packed with an electroactive material is transformed by its oxidation/reduction. Eqn [5] depicts this process whereby a coating (C) is switched between its reduced and oxidized forms with the concomitant expulsion or uptake of anions (A^-). The analogous reaction:

can be written for coatings that involve cations as counterions. Thus, the charge density of the ion-exchange sites on a stationary phase can be tuned

Figure 2 Idealized representations of the interactions of donor (D) and acceptor (A) analytes with a conductive stationary phase as a function of applied potential (E_{app}). Collectively, changes in applied potential alter the extent of the interaction of such analytes through a change in the surface charge of the stationary phase. At applied potential greater than the potential of zero charge (pzc), the stationary phase has a net positive surface charge and therefore a greater acceptor strength. This increase results in an increase in the attractive interaction between the stationary phase and a donor analyte. The converse applies as the applied potential becomes more negative than the pzc. In this case, the donor strength of the stationary phase increases, and the attractive interaction between the stationary phase and an acceptor analyte increases.

through changes in applied potential. Several intriguing features of this strategy have been described.

Electrochemically modulated liquid chromatography, therefore, presents a broad range of tactics that can, as demonstrated in the next section, be exploited in tackling the many separation challenges faced in the analytical laboratory.

Applications

This section presents a few examples of the capabilities of the technique, including the separation of aromatic compounds, pharmaceutical agents, and chiral compounds. The use in a concentration format is also described.

Aromatic Sulfonates

The earliest demonstration of the ability of electrochemically modulated liquid chromatography to separate complex mixtures at performance levels that rivaled conventional liquid chromatographic separations used porous graphitic carbon as the column packing and the aromatic sulfonates in Table 1 as analytes. Examples are presented in Figure 3. These results show that: (1) the retention for all of the analytes increases as the applied potential moves positive, (2) the retention of all the analytes (Figure 4) exhibit a linear dependence on applied potential, (3) the magnitude of the change in retention differs between analytes, and (4) all six analytes in the mixture are baseline resolved at +0.5 V. These results confirm that the analytical figures of merit (e.g. resolution and retention time) can be readily manipulated by changes in applied potential, and that the change in the surface charge of the stationary phase plays a key role in altering the extent of retention.

It is also possible to affect such separations by manipulating the applied potential during analyte elution, a strategy that parallels temperature pro-

Figure 3 Separations of a mixture of aromatic sulfonates (see Table 1) using a porous graphitic carbon stationary phase at +0.50 V (A), open circuit (B), and -0.60 V (C). The mobile phase was water (0.1 M LiClO₄, 0.1% TFA) and acetonitrile (0.1 M LiClO₄) (88 : 12, v/v). The flow rate was 0.90 mL min⁻¹. gramming in gas chromatography. Figure 5 demonstrates this possibility whereby a linear voltage ramp is imposed upon the stationary phase from +0.3 V to -1.0 V immediately upon sample injection. This strategy increases the resolution of the compounds that eluted early at the open circuit potential (i.e. the condition used in conventional liquid chromatography) by increasing their retention. At the same time, this waveform decreases the retention and narrows the bands for those compounds eluting much later in the open circuit separation. There is also a notable decrease in the time required to complete the separation (~4 min). Thus, a stationary phase gradient offers a pathway for the optimization of separations.

Table 1 Chemical structures and labelling schemes of the aromatic sulfonate derivatives

Compound	Acronym	A
1	ABS	NH ₂
2	HBS	OH
3	BS	H
4	TBS	CH ₃
5	CBS	Cl
6	BAS	COOH

Corticosteroids

Separations of structurally similar compounds can readily be fine tuned using electrochemically modulated liquid chromatography. The challenge presented by the separation of four corticosteroids, [I]–[IV], at a porous graphitic carbon stationary phase is a particularly intriguing example.

The complication with this mixture is the discrimination between structures containing differing numbers of double bonds (e.g. prednisone vs. cortisone) and/or small differences in the identity and number of substituents (e.g. cortisone vs. hydrocortisone). On bonded reversed phases, compounds with subtle differences in functionality generally exhibit greater differences in retention than those that differ by the number of double bonds. The converse is often more important for separations on porous graphitic carbon, which possesses π -electron sensitivity superimposed upon reversed phase characteristics. Thus,

Figure 4 Plots of $\log k$ vs. applied potential (E_{app}) for the separations of the mixture of aromatic sulfonates (see Table 1) between +0.50 V and -1.00 V. Note that the values of HBS extend only from +0.50 V to -0.10 V because of its electroreduction which occurs at an E_{app} between -0.10 and -0.20 V. strategies that would enhance the sensitivity of carbonaceous materials toward substituent differences, would improve their applicability as packings especially as they are more stable than many of the bonded phases when exposed to strongly acidic and strongly alkaline solutions.

The chromatograms in Figure 6 present the separations of the four compounds as a function of applied potential using a porous graphitic carbon stationary phase. At the open circuit potential, the separation is only marginally effective in resolving the four compounds. Changes in the applied potential, however, have a marked influence on the separation. Interestingly, the retention of prednisone and prednisolone increase as the applied potential becomes more negative, with that for prednisone becoming greater than that for prednisolone. This difference transposes the elution order for the two compounds. The same general dependencies for the retention of cortisone and hydrocortisone are observed. In contrast to the aromatic sulfonates, the supporting electrolyte can compete in some instances with the analyte for binding sites on the stationary phase, leading to retention dependencies that are nonlinear with respect to changes in applied potential. As a result of the combined effect of these dependencies, all four components are fully resolved at -700 mV, with a total elution time of ~ 10 min. Thus, separations based on manipulating the applied potential provide an effective and

Figure 5 Separation of the six-component mixture of aromatic sulfonates (see Table 1) on a porous graphitic carbon stationary phase obtained by applying a linear voltage ramp from +0.30 V to -1.00 V. The voltage ramp was initiated immediately upon sample injection at 10 mV s^{-1} . The mobile phase consisted of aqueous 0.1 M LiClO_4 with 1.5% acetonitrile. The flow rate was 0.75 mL min^{-1} and the analyte concentrations were $\sim 200 \text{ ppm}$. The shift in the baseline reflects the gradual decrease in the interfacial concentration of the ClO_4^- anion of the supporting electrolyte in the mobile phase as the applied potential becomes more negative. The background baseline gradually returns to its initial value in $\sim 10 \text{ min}$. facile means to tackle the challenges posed by the strong structural similarity of these compounds.

Chiral Compounds

This technique can also be applied to separations of racemic mixtures. These separations, usually accomplished with a chiral selector either immobilized onto a stationary phase or as an additive to a mobile phase, are critical to pharmaceutical areas because therapeutic efficacy is often enantiomerically specific. However, the high level of structural discrimination required to separate optical isomers dictates the use

of a variety of stationary-mobile phase combinations. This separation can be realized by the reversible electrosorption of a chiral compound added to the mobile phase, a process that converts an achiral column into a chiral column. The concept is illustrated in Figure 7, using β -cyclodextrin as the chiral mobile phase additive. The choice of this additive reflects the notable enhancement of the interactions between hydroxyl functionalities and a carbonaceous packing as the applied potential becomes increasingly positive.

Results are presented in Figure 8 for the separations with and without the chiral selector present as a mobile phase additive at several different applied

Figure 6 Separations using EMLC of a mixture of the mixture of prednisone [I], prednisolone [II], cortisone [III], and hydrocortisone [IV] at a porous graphite carbon stationary phase as a function of applied voltage: +500 mV, open circuit (i.e. +440 mV), +300 mV, 0 mV, -200 mV, -400 mV, -700 mV. All applied voltages are given with respect to an Ag/AgCl (saturated NaCl) electrode. The mobile phase was composed of two components: water (0.1 M HClO_4)/acetonitrile (0.1 M LiClO_4) 50:50 (v/v). The flow rate was 0.90 mL min^{-1} . (Reproduced with permission from Ting EY and Porter MD (1997) *Analytical Chemistry* 69: 675–678. Copyright ACS Publications.)

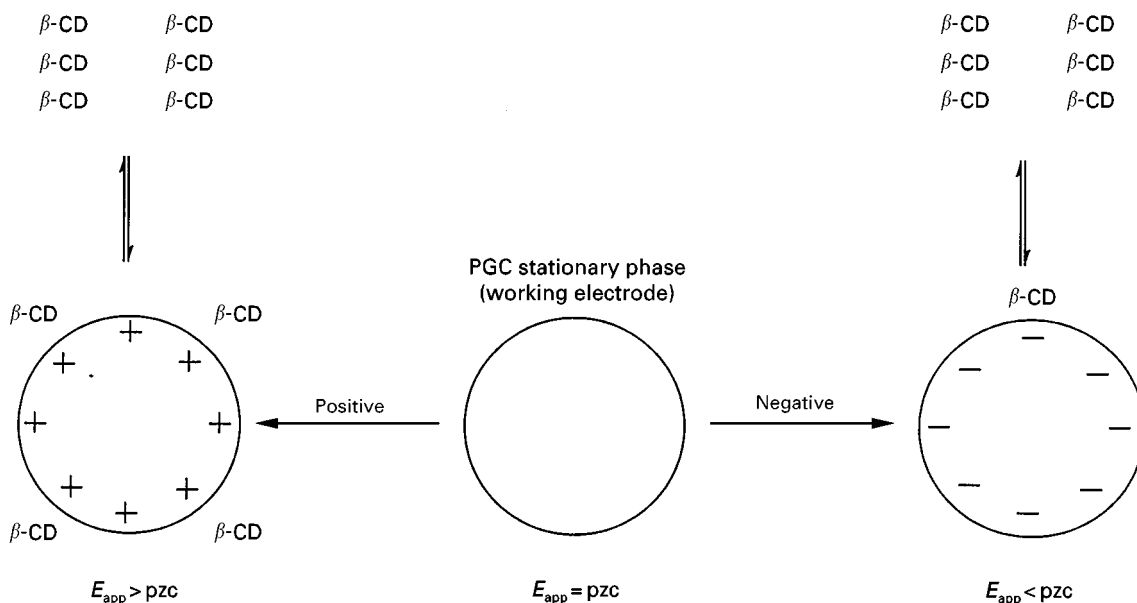

Figure 7 Idealized depiction of the electrosorption process of β -cyclodextrin (β -CD) onto porous graphite carbon (PGC). pzc , potential of zero charge.

potentials. The sedative hexobarbital is used as the chiral analyte. As expected for an achiral system, there is no detectable separation of enantiomers in Figure 8A. Furthermore, the retention of the sedative increases as the applied potential becomes more negative. This trend is consistent with the dominant acceptor character of this compound because of its protonation at the mobile phase ($pH \sim 2$).

Marked differences in the separations are found when β -cyclodextrin is added to the mobile phase. Figure 8B shows the results; the presence of the additive results in a separation of the hexobarbital enantiomers at several applied potentials. Enantiomeric separations are evident at -1.0 , 0.0 , and $+0.5$ V, with the highest resolution at $+0.5$ V. There is no observable enantiomeric separation for -0.5 V. Experiments in which an excess of one enantiomer was added to the mixture reveal the enantiomeric separation is controlled at the more negative applied potentials by interactions with the chiral additive in the mobile phase, and at the more positive applied potentials by interactions with the electro-sorbed chiral selector.

Experiments have also shown that the electrosorption-based modification of the porous graphitic carbon phase is reversible. This observation suggests that electrosorption may serve as a versatile means for altering the surface composition of conductive stationary phases whereby a chiral column for enantiomeric separations could, for example, be readily converted to a column with reversed phase character by the electrosorption of another mobile phase addi-

tive (e.g. a long alkyl chain alcohol). This intriguing strategy offers the possibility of requiring only one column for the separation of a wide range of complex mixtures.

Concentration

Another intriguing application of this technique is sample concentration. This approach takes advantage of the ability to modulate the capacity of a stationary phase, for example, by changes in the oxidation state of an electrochemically transformable stationary phase (e.g. eqn [5]). This strategy is similar to that employed in solid-phase extractions except that changes in applied potential rather than changes in solvent can be used to concentrate and then strip the analyte from the column.

An example of this strategy is the concentration of the dansylated amino acid tryptophan using a non-porous carbon stationary phase that is coated with a thin film of polypyrrole. Polypyrrole, which can be polymerized electrochemically onto a wide range of electrode materials, can be switched between its oxidized and reduced forms with the concomitant uptake or expulsion of anions, as represented in Figure 9. Thus, changes in applied potential transform the stationary phase between one devoid of ion-exchange sites to one with a large number of exchange sites. This transformation is evident in the cyclic voltammetric curve shown in Figure 10. This curve demonstrates the change of the coating from its neutrally charged (reduced) form at the more negative

Figure 8 Separations of hexobarbital enantiomers (*d* and *l*), using a mobile phase of 20% acetonitrile and 80% water (0.1 M LiClO₄, 20 mM phosphate buffer (pH ~ 2)), a flow rate 0.9 mL min⁻¹, a detection wavelength of 220 nm, and an Ag/AgCl (saturated NaCl) reference electrode. (A) Separations in mobile phase devoid of β -cyclodextrin at -1.0 V, -0.5 V, 0.0 V and +0.5 V. (B) Separations with 15 mM β -cyclodextrin as a mobile phase additive at -1.0 V, -0.5 V, 0.0 V and +0.5 V. The concentration of hexobarbital is ~500 ppm, and the injection volume was 0.5 μ L. (Reproduced with permission from Ho MK, Wang S and Porter MD (1998) *Analytical Chemistry* 70: 4314–4319. Copyright ACS Publications.)

values of applied potential to its cationic (oxidized) form as the applied potential becomes increasingly positive.

Figure 9 Electrochemical switching of polypyrrole between its oxidized and reduced forms showing the respective uptake or expulsion of an anion A⁻.

Figure 10 Cyclic voltammetric curve for a nonporous glassy carbon packing that has been coated with a thin film of polypyrrole in 0.10 M sodium benzoate. A silver wire is used as a quasi-reference electrode, and the scan rate was 5 mV s⁻¹. (Reproduced with permission from Deinhamer RS, Shimazu K and Porter MD (1995) *Journal of Electroanalytical Chemistry* 387: 35–46. Copyright Elsevier SA.)

Figure 11 presents the details of the experiment by showing the breakthrough curve for the concentration process. The experiment begins by passing a mobile phase containing dansylated tryptophan through the column continuously while the applied potential is held at -1.00 V. The applied potential is then stepped to and held at 0.00 V to oxidize the coating to its cationic form. Upon stepping potential to 0.00 V, the absorbance of the eluent rapidly decreases to the value of the acetate mobile phase, reflecting the exhaustive uptake of the amino acid by the coating. After ~67 min, the absorbance increases slowly to the value initially observed at -1.00 V.

This increase signals the saturation of the coating by the uptake of the amino acid from the highly dilute solution; the coating is fully saturated in 72.5 min. After saturation, the applied potential is stepped back to -1.00 V to reduce the coating to its neutral form, and strip the amino acid from the column in a narrow elution band. An analysis of the data gives a concentration factor of ~33 and a recovery of ~98%. Thus, this strategy offers an alternative approach to the solvent elution processes used in most other concentration techniques in that the stripping of an analyte from the column can be facilitated by a change in applied potential, opening the possibility of large reductions in the volumes of generated wastes.

Figure 11 Breakthrough curve showing the concentration of a 1.6 ppm solution of dansylated tryptophan at a polypyrrole stationary phase. The applied potential was initially held at -1.00 V, stepped to 0.00 V for 72.5 min, and then stepped back to -1.00 V. The mobile phase consisted of 1.6 ppm dansylated amino acid tryptophan in 10 mM pH 6 acetate buffer. Future Developments

Electrochemically modulated liquid chromatography is emerging as a valuable addition to the arsenal of liquid chromatographic techniques used in tackling the many challenges encountered in the day-to-day operations of the analytical laboratory. Advances in this area will continue with improvements in column design that reduce the equilibration time to changes in applied potential. Such developments will enhance the ability of the analyst to manipulate separations by dynamically altering the applied potential during analyte elution.

There are also several intriguing opportunities in the creation of separation formats using new types of stationary phases. Other types of conducting phases based, for example, on electrochemically transformable coatings offer pathways to manipulate separations by variations in the porosity of a coating which can be affected by the size of the dopant ion used in the electrochemical coating process. Variations in porosity may add size discrimination to the selectivity of the separation process. In addition, the incorporation of functional groups as substituents on the monomer precursors used for polymer formation can be exploited to design coating with hydrophobicity–hydrophilicity differences.

Another area of fruitful development lies in the coupling of this technique to other detector formats. Mass spectrometry, for instance, has proven invaluable as a detector in a wide range of chromatographic applications. The ability of electrochemically modulated liquid chromatography to address separations

that require the use of gradient-elution strategies may overcome the associated problems of a continuing changing background when using electrospray mass spectrometry. Enhancements may also be realized by electrochemically transforming an analyte to a form that improves not only its separation but also its response to conventional optical detection formats. These developments, coupled with systematic explorations of the interactions operative in the many retention mechanisms, promise to stimulate the widespread interest in this new mode of liquid chromatographic separations.

Introduction

High performance liquid chromatography (HPLC) is an established technique with a vast number of stationary phases available, but the efficiency is ultimately limited by the size of the particles used to pack the columns. Theory shows that for the highest efficiency the particles should be of a much smaller diameter than those in current use, but a significant move in this direction is constrained by the pressure required from the pumping system used to deliver the mobile phase. Capillary electrochromatography (CEC) uses an electric field rather than hydraulic pressure to drive the mobile phase through the packed bed of stationary phase. Since the resulting flow profile is plug-like rather than parabolic, very high efficiencies can be achieved.

Theory

The ability to drive a liquid through a packed capillary under the influence of an electric field was first described by Pretorius in 1974, but a lack of the necessary hardware at the time meant that his suggestion was not followed up. Pretorius showed that the linear velocity of a liquid (u) under electrical flow conditions was given by the equation:

$$u = \frac{\varepsilon E \zeta}{4\pi\eta} \quad [1]$$

where E is the applied electrical field in V cm^{-1} ; ε is the dielectric constant (dimensionless); ζ is the zeta potential in volts; and η is the viscosity of the liquid in $\text{kg m}^{-1} \text{s}^{-1}$.

Pretorius estimated from eqn [1] that, with voltages up to 1500 V cm^{-1} , it should be possible to

generate linear velocities of 0.1 to 1 cm s^{-1} , which are similar to those used in modern HPLC. He also noted that eqn [1] is independent of particle diameter, which means that the flow rate could be maintained in a column packed with very fine material. When the various contributions to column plate height are summed and plotted against linear velocity, it can be seen that the overall dispersion in an electrically driven system is approximately half that of a corresponding pressure-driven system. This is almost entirely due to a dramatic decrease in the contribution of the eddy diffusion term in the electrically driven system, as illustrated in **Figure 1**.

The driving force in electrochromatography results from the electrical double layer that exists at any liquid–solid interface. The electrical double layer inside a fused silica capillary filled with an electrolyte is shown in **Figure 2**.

Under alkaline conditions, the surface silanol groups of the fused silica become ionized, leading to a negatively charged surface. This surface will have a layer of positively charged ions in close proximity that is relatively immobile. This surface layer of ions is called the Stern layer. The remainder of the excess charge, constituting the Goüy layer, is solvated and has the characteristics of a typical solvated ion. This layer extends into the bulk of the liquid and is the so-called double layer. The concentration of ions in the double layer is relatively small compared to the total ion concentration and falls off exponentially from the capillary surface, as does the electrical potential, which is proportional to the charge density. The potential at the boundary between the Stern layer and the diffused Goüy double layer is known as the zeta potential, ζ , and ranges from 0 to 100 mV . As the charge density drops off with distance from the surface, so does the zeta potential. The distance from the immobile layer to a point in the bulk liquid at which the potential is 0.37 of that at the interface between the Stern layer and the diffuse layer is defined as the thickness of the double layer, denoted by δ . The

Figure 1 Contributions to plate height in (A) a pressure-driven system (HPLC) and (B) an electrically driven system (electrochromatography). HETP, height equivalent to one theoretical plate. (Reprinted from Dittmann MM and Rozing GP (1996) Capillary electrochromatography – a high efficiency micro-separation technique. *Journal of Chromatography A* 744: 63–74 with kind permission from Elsevier-NL.)

equation describing δ is as follows:

$$\delta = \frac{\varepsilon_r \varepsilon_0 R T^{1/2}}{2 c F^2} \quad [2]$$

where ε_r is the dielectric constant or relative permittivity of the medium; ε_0 is the permittivity of a vacuum ($8.85 \times 10^{-12} \text{ C}^2 \text{ N}^{-1} \text{ m}^2$); R is the gas constant ($8.314 \text{ J K}^{-1} \text{ mol}^{-1}$); T is the temperature in Kelvin; c is the molar concentration of the electrolyte; and F is the Faraday constant ($96\,500 \text{ C mol}^{-1}$).

Using the above equation with water ($\varepsilon_r = 80$), the thickness of the electrical double layer for a 1:1 electrolyte at a concentration of 0.001 mol L^{-1} in water would be 10 nm, while at a concentration of 0.01 mol L^{-1} it would be 1 nm.

Electroosmotic flow (EOF) in a capillary arises when an electric field is applied tangentially along the length of the column. This causes the ions in the diffuse (Gouy) layer that are not absorbed into the Stern layer to migrate towards the cathode. Shearing will occur within this region and electroosmosis will result because the core of liquid within this sheath

Figure 2 Electrical double layer. Origin of electroosmotic flow (EOF) in a fused silica capillary. (By permission of the author.)

will also be transported to the cathode. Because shearing only occurs within the diffuse layer, the resulting flow profile is plug-like and its velocity is independent of the capillary diameter (d), provided that $d \geq 10\delta$ (d is usually $> 20\delta$).

If d approaches δ , then double layer overlap will occur and the electroosmotic flow will be considerably reduced, taking on a parabolic profile. In the case of packed capillaries, the capillary diameter is replaced in the equation by the mean channel diameter. Thus for aqueous electrolytes between 0.001 mol L^{-1} and 0.01 mol L^{-1} there would be no double layer overlap as long as $d_p \geq 40\delta$.

If we assume a value of 10 nm for δ in a 0.001 mol L^{-1} aqueous solution, then $d_p = 0.4 \mu\text{m}$ and use of these small-diameter particles should give a dramatic increase in column efficiency. Since typical silica-based reversed-phase packing materials also contain silanol groups, these also contribute to the overall EOF, as illustrated in Figure 3.

Another important consideration in CEC is the relationship between the linear velocity and concentration of the electrolyte. Since u is directly propor-

Figure 3 EOF at high pH in a capillary packed with standard HPLC material (e.g. C_{18} , C_8). (By permission of the author.)

tional to the zeta potential, which itself decreases with increasing electrolyte concentration, it is an important variable to consider during method development. The effect of electrolyte concentration on the zeta potential has been measured using 5 μm Hypersil ODS. The results showed that $10^{-4} \text{ mol L}^{-1} \text{ NaNO}_3$ had a zeta potential of $\sim 50 \text{ mV}$, while at $10^{-3} \text{ mol L}^{-1}$ the potential was $\sim 45 \text{ mV}$ and at $10^{-2} \text{ mol L}^{-1}$ it was $\sim 25 \text{ mV}$. When plate height and linear velocity were plotted against NaH_2PO_4 concentration, the reduced plate height was lowest at $10^{-3} \text{ mol L}^{-1}$ and the linear velocity altered little over the range $4 \times 10^{-5} \text{ mol L}^{-1}$ to $2 \times 10^{-2} \text{ mol L}^{-1}$. The best overall performance, i.e. the lowest values of plate height (H), at high EOF would be achieved at electrolyte concentrations of $c. 0.002 \text{ mol L}^{-1}$.

Experimental Considerations

If higher concentrations of buffer are used, particularly with high concentrations of organic solvent, then bubble formation can become a problem. This can be overcome by operating the whole capillary under pressure. Figure 4 is a schematic diagram showing such a pressurized apparatus.

The packing of small-diameter particles into narrow capillaries represents an enormous challenge. The initial stage is the formation of a suitable retaining frit, which must be capable of retaining particles of not more than $1 \mu\text{m}$ and also capable of withstanding pressures of the order of 10 000 psi (68 000 kPa). Outline details of how to form such frits can be found in the literature. The frits must have a good porosity if the packing process is to be successful; porosity can be tested with a conventional HPLC pump at 6000 psi (41 000 kPa) and a flow of water of

1 mL min^{-1} . For a good frit the pressure should rise to 6000 psi fairly rapidly and then stop due to the pressure cut-out. An ideal frit is one where the pressure decays to zero over a period of 10–20 s. If the pressure decay is much quicker then the frit has probably failed; if the decay is very slow then the frit is not porous enough for efficient column packing. Once a satisfactory frit has been formed, then the capillary can be slurry packed as outlined in Figure 5.

Although the packed capillary contains water it is not necessary to condition it with mobile phase since there is a sufficient EOF to allow the mobile phase to be pumped into the system. Once a steady current has been established the column is ready for use.

Applications

Figure 6 shows the separation of the steroid fluticasone propionate from two closely related impurities using micellar electrokinetic chromatography (MEKC) with sodium dodecyl sulfate (SDS) as the micelle while Figure 7 shows the corresponding HPLC trace using 3 μm Spherisorb ODS-1 stationary phase with gradient elution (impurity 3 was not present in the MEKC experiment).

If the sample is analysed by CEC with the same batch of 3 μm Spherisorb ODS-1, then the chromatogram shown in Figure 8 is obtained. Apart from a reversal in elution order from the MEKC/HPLC to the CEC the latter is extremely efficient with peak 3 in the CEC trace exhibiting an efficiency of almost $4 \times 10^5 \text{ plates m}^{-1}$ with a reduced plate height of 0.9.

If the electrolyte is changed from phosphate to borate and the organic content increased from 75 to 80%, then the chromatogram shown in Figure 9 is obtained. Although the capillary length has been increased, the analysis time has been reduced significantly. Also, a peak previously undetected has now shown up between peaks 1 and 2.

Increasing the organic content of the electrolyte can drastically reduce run times, but in order to maintain high efficiencies it is desirable to work at high buffer concentration. To meet this criterion it is necessary to work with so-called biological buffers since traditional inorganic buffers are insoluble in high concentrations of organic solvents. Figure 10 shows the fast, highly efficient analysis of the three impurity peaks from the parent steroid in less than 11 min using a mobile phase containing 0.1 mol L^{-1} Tris buffer (2-amino-2-hydroxymethylpropane-1,3-diol).

Figure 11 shows the chromatogram of a crude sample of a prostaglandin, GR63779X, obtained by using an unadjusted phosphate buffer on a 3 μm Spherisorb ODS-1 phase, while Figure 12 is the same

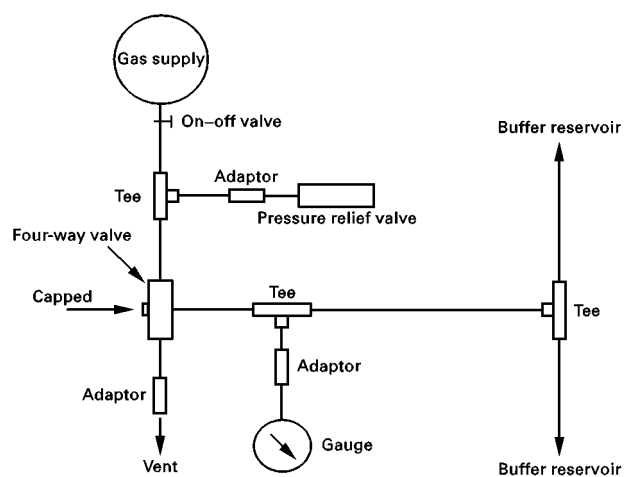

Figure 4 Schematic layout of the pressurization system for electrochromatography. (By permission of the author.)

sample run under identical conditions on a 1.5 μ m Zorbax C_8 column.

The expected increase in efficiency on going from 3 μ m to 1.5 μ m particles has not been realized. The efficiency for the peak eluting at 20 min on the smaller-particle Zorbax column is about 300 000 plates m^{-1} with a reduced plate height of 1.6. This is not as good as the figures for the 3 μ m column for two reasons: first, there is the difficulty in packing the smaller particles, and second, Zorbax itself is a difficult material to pack. However, for the two early

eluting peaks the 1.5 μ m Zorbax column gives much better peak shapes and slightly different selectivity. **Figure 13** shows a highly efficient separation of an angiotensin compound from 13 impurities. Apart from the two late emerging compounds, all the peaks are symmetrical with no apparent evidence of peak tailing. In contrast many of the compounds in this mixture gave tailing peaks when run on an HPLC column containing the same stationary phase. This may be due to the fact that the CEC separation was at high pH while the HPLC separation was at a pH less than 5. Experience has shown that it is possible to run columns under electrodrive conditions at a much higher pH than is possible in HPLC without any deterioration in performance and often with a considerable improvement in separation.

Figure 10 Rapid separation of fluticasone from related impurities by CEC with a Tris buffer. Column, 40 cm \times 50 μ m i.d. packed with 3 μ m ODS-1; detection at 238 nm, 0.05 au/s; voltage, 30 kV; temperature, 30°C; carrier, 90% acetonitrile/10% 0.1 mol L⁻¹ Tris; injection, 0.05 min at 10 kV.

Cephalosporins are a class of antibiotic compounds. As well as the chiral centre in the β -lactam ring, the compound shown in **Figure 14** possesses a chiral centre in the ester group on the adjacent six-membered ring, giving rise to a pair of diastereoisomers. In addition the oxime group can be in one of two positions – either the *syn* (*E*) or the *anti* (*Z*) – both of which give rise to isomers. Both pairs of diastereoisomers are readily resolved on the 3 μ m Spherisorb ODS-1 column with a length of 40 cm. The use of such a column length for HPLC would be impractical because the pressure requirements would be beyond the range of current instruments. Since there is no pressure drop in CEC, the use of long columns presents no practical problems.

If the extremely high efficiencies obtained with CEC for achiral compounds could be matched with

chiral compounds, then there would be less need to achieve high α values in order to separate the isomers. **Figures 15** and **16** show the separation of bendroflumethiazide and hexobarbital on an α -glycoprotein and a Cyclobond stationary phase, respectively. Although large α values are obtained with these columns, the overall efficiencies are extremely poor. This is possibly due to column overload, since these phases have a low sample capacity.

Nearly all CEC separations to date have been carried out on C₁₈ or C₈ phases. However, because EOF drops off substantially below pH 6, most studies have been carried out above pH 7 and as a result most CEC has been for neutral molecules. One way of promoting EOF at lower pH values is by the use of columns packed with a strong cation exchanger (SCX); such

Figure 9 Separation of fluticasone from related compounds by CEC with a borate buffer. Column, 60 cm \times 50 μ m i.d. PC20 packed with 3 μ m ODS-1; detection at 238 nm, 0.05 au/s; voltage, 30 kV; temperature, 30°C; carrier, 80% acetonitrile/20% 5 mmol L⁻¹ borate, pH 9; injection, 0.4 min at 30 kV.

Figure 11 Separation of a prostaglandin from related impurities by CEC. Column, 60 cm \times 50 μ m i.d. packed with 3 μ m ODS-1; detection at 270 nm, 0.05 au/s; voltage, 30 kV; temperature, 35°C; carrier, 70% acetonitrile/30% 0.1 mol L⁻¹ Na₂HPO₄; injection, 0.04 min at 30 kV. (By permission of the author.)

Figure 12 Separation of a prostaglandin from related impurities by CEC with a column packed with 1.5 μm C_8 silica. Column, 40 cm \times 50 μm i.d. packed with 1.5 μm Zorbax; detection at 270 nm, 0.05 a.u.; voltage, 30 kV; temperature, 30°C; carrier, 70% acetonitrile/30% 0.1 mol L⁻¹ Na₂HPO₄; injection, 0.04 min at 20 kV.

a material has been used for the CEC of neutral and charged analytes. The SCX used (manufactured by Phase Separations Ltd, Deeside, UK) had a sulfonic acid group linked to 3 μm silica via a propyl group to give a loading of 0.031 mEq g⁻¹.

Figure 17 shows the structures of a group of tricyclic antidepressants. Because of the highly basic nature of these compounds, with typical pK_a values of around 8, severe tailing is encountered with HPLC and even the new base-deactivated phases made from ultrapure silica still give some tailing.

When a test mixture containing bendroflumethiazide and four of the antidepressants was analysed on a Spherisorb ODS-1 capillary, only the neutral bendroflumethiazide eluted (Figure 18). However, CEC

Figure 13 Separation of an angiotensin compound from impurities by CEC at a relatively high pH. Column, 30 cm \times 50 μm i.d. packed with 3 μm ODS-1; detection at 220 nm, 0.03 a.u.; voltage, 30 kV; temperature, 28°C; carrier, 76% acetonitrile/H₂O in 2 mmol L⁻¹ Na₂HPO₄ buffer, pH 7.3; injection, 0.4 min at 20 kV.

Figure 14 Separation of diastereoisomers by CEC. Column, 40 cm \times 50 μm i.d. packed with 3 μm ODS-1; detection at 276 nm, 0.03 a.u.; voltage, 30 kV; temperature, 30°C; carrier, 50% acetonitrile/50% 0.01 mol L⁻¹ Na₂HPO₄; injection 0.2 min at 20 kV.

analysis at low pH on the 3 μm SCX phase gave unexpectedly high efficiencies. Figure 19 shows the separation of three tricyclic antidepressants on the cation exchange phase at pH 3.5. It is noticeable in this chromatogram that the neutral compound bendroflumethiazide, despite eluting first, gives a significantly broader peak than the later eluting compounds. This suggests that some form of focusing effect is taking place. Plate numbers on this phase have been measured in excess of 8×10^7 , which is many orders of magnitude above that explicable by current theory.

Attempts to use a mixed-mode column with a C₁₈ ligand and a -SO₃H functional group attached to the same silica particle were not successful. When the antidepressant test mixture is injected onto the mixed-mode column at both pH 9.8 and pH 5.7, only

the neutral bendroflumethiazide is eluted. Similar results were obtained with a mixed-mode phase with a C_6 chain. It is believed that the hydrophobic ligands

Figure 17 Structures of some tricyclic antidepressants separated by CEC.

Figure 18 CEC of bendroflumethiazide and four tricyclic antidepressants by CEC on a $3\text{ }\mu\text{m}$ ODS-1 column. Detection at 210 nm, 0.05 aufs root temperature 0.2; voltage, 30 kV; temperature, 30°C ; carrier, 70% acetonitrile/30% 0.01 mol L^{-1} Na_2HPO_4 , pH 9.8 unadjusted; injection, 0.3 min at 3 kV. Peak 1 represents bendroflumethiazide. Nortriptyline, clomipramine, methdilazine and imipramine were not eluted.

collapse onto the $-\text{SO}_3\text{H}$ groups and shield them from participation in the focusing process. If a strong cation exchanger is produced, using a different link from the propyl group used for the original material, then the focusing effect returns. **Figure 20** shows the electrochromatogram of methdilazine, clomipramine and imipramine on a column containing a stationary phase where the sulfonic acid group is attached to the silica via a phenyl group. Once again, highly efficient separations are obtained. Methdilazine now elutes before clomipramine, whereas on the propyl $-\text{SO}_3\text{H}$ phase elution was the other way round.

Nonporous materials are used in HPLC for the analysis of highly hydrophobic compounds that

Figure 19 CEC of bendroflumethiazide and three tricyclic antidepressants on a $3\text{ }\mu\text{m}$ Spherisorb SCX column. Detection at 220 nm, 0.045 aufs; voltage, 30 kV; temperature, 30°C ; carrier, 70% acetonitrile/30% 0.05 mol L^{-1} Na_2HPO_4 , pH 3.5; injection, 0.5 min at 2 kV.

Figure 20 CEC separation of three tricyclic antidepressants on an SCX column with the SO_3H group attached to the silica via a phenyl group. Packed length = 40 cm, total length = 56 cm; voltage, 30 kV; detection at 210 nm; 0.02 aufs; carrier, 70% acetonitrile/30% $0.01 \text{ mol L}^{-1} \text{NaH}_2\text{PO}_4$, pH 2.3; injection, 0.4 min at 2 kV.

would normally be too strongly retained on conventional porous reversed-phase packings. Micropell C_{18} , made by Horváth (Yale, USA), has been used successfully for CEC with relatively small molecules even though there is little retention because of the very small surface area. **Figure 21** shows the separation of the neutral diol, GR5788X, from the dibenzyl compound, GR57994X, in less than 4 min on a 40 cm capillary packed with this $2 \mu\text{m}$ nonporous phase.

Conclusion

Capillary electrochromatography is a highly promising technique that couples the advantages associated with capillary electrophoresis with those of HPLC. Theory predicts a 2- to 3-fold increase in efficiency on going from an HPLC pressure-driven system to a CEC electrically driven system. Because there is no pressure drop across the capillary column in CEC, it is possible to use long columns that would require prohibitively high pressures if used in pressure-driven systems. Examples have been given of separations by CEC on 40 cm long capillaries giving efficiencies of $4 \times 10^5 \text{ plates m}^{-1}$. This is equivalent to 160 000 effective plates, which is a factor of about 15 times greater than that currently available in HPLC.

The development of stationary phases that allow CEC to be used over a wider pH range will allow the analysis of mixtures containing neutral and charged

Figure 21 CEC separation on a nonporous phase, Micropell- C_{18} . Voltage, 30 kV; temperature, 30°C ; detection at 210 nm; carrier, 70% acetonitrile/30% $2 \text{ mmol L}^{-1} \text{Na}_2\text{HPO}_4$, pH 7.0; injection, 10 s at 2 kV.

species and will offer a viable complementary technique to HPLC and capillary electrophoresis.

Enhanced Fluidity Liquid Chromatography

S. V. Olesik, Ohio State University,
Columbus, OH, USA

Introduction

High performance liquid chromatography (HPLC) is often the method of choice for the separation of nonvolatile solutes. LC commonly exhibits longer analysis times, larger pressure drops and lower efficiency than either supercritical fluid chromatography (SFC) or gas chromatography (GC). The greater viscosities and lower diffusivities of liquids compared to those of supercritical fluids or gases are the primary cause of these differences in the three types of chromatography. The ideal mobile phase for a chromatographic separation of nonvolatile solutes would combine the positive attributes of liquids and supercritical fluids. That is, a solvent with low viscosity, high diffusivity and high solvent strength is desirable. Enhanced-fluidity liquid mixtures are solvents that have these attributes. These solvents are prepared by dissolving large proportions of liquefied gases, such as CO₂, in commonly associated liquid solvents such as methanol.

To date, enhanced-fluidity mixtures such as methanol-CO₂, methanol-CO₂-H₂O, tetrahydrofuran-CO₂, hexane-CO₂, methanol-fluoroform and methanol-fluoroform-H₂O have been used to improve the performance in a range of different types of liquid chromatographies.

Properties of Enhanced-Fluidity Liquid Mixtures

When a liquefied gas is added to an associated solvent, the viscosity of the resultant mixture decreases. For example, Figure 1 shows the variation in the viscosity of methanol-CO₂ and solute diffusivity as a function of the proportion of added CO₂ at 25°C. The addition of 50% v/v CO₂ causes the viscosity of the mixture to lower to a value that is approximately 70% of the viscosity of methanol. The viscosity, η , of a liquid is typically inversely related to the diffusion coefficient of a solute at infinite dilution, D_{12} , as described in eqn [1]:

$$D_{12}\eta^p = AT \quad [1]$$

where A and p are constants that are characteristic of the solute and T is the absolute temperature. There-

fore, Figure 1 shows that the addition of 50% v/v CO₂ causes the diffusion coefficient of benzene to increase by approximately a factor of 2.

If liquefied gas addition and temperature elevation are combined, improvements in mass transport are substantial. For example, at 58°C with a 0.49 : 0.21 : 0.30 mol fraction methanol-H₂O/CO₂ mixture, the diffusion coefficient of benzene increases ninefold relative to that in the same methanol-H₂O mixture at 26°C. Without temperature elevation, the diffusion coefficient of benzene increases by a factor of 2 by adding 0.30 mol fraction CO₂ to the 0.70 : 0.30 mol ratio methanol-H₂O mixture (Figure 2).

These improvements in the transport properties of the liquid mixtures are only advantageous if the solvent strength of the mixtures remains high when the liquefied gas is added. Figures 3 and 4 show the variation of the hydrogen bond acidity, hydrogen-bond basicity and dipolarity for methanol-CO₂ mixtures as measured by Kamlet-Taft α , β , and π^* solvent strength parameters. Clearly the hydrogen bond acidity and basicity of the methanol-CO₂ mixtures is similar to that of methanol, even with 70% added CO₂. The dipolarity of the mixture decreases faster than the hydrogen bond acidity or basicity with added CO₂. However, the dipolarity remains relatively high, even with 50% added CO₂. Data collected on a number of enhanced-fluidity mixtures have shown that often as much as 50% liquefied gas can be added to the organic solvent without significantly affecting the solvent strength.

Theory

To demonstrate the importance of mass transfer coefficients in liquid chromatography, the van Deemter equation (eqn [2]) is used to model the variation of the chromatographic band dispersion, H , in packed column as a function of linear velocity, u . A is a constant that measures the contribution to band dispersion caused by multiflow paths, B describes the band dispersion caused by longitudinal diffusion and C describes the band dispersion caused by nonequilibrium in both the stationary and mobile phases:

$$H = A + \frac{B}{u} + \sum C_i u \quad [2]$$

By taking the derivative of the van Deemter equation with respect to u , equating the derivative to zero, and substituting in appropriate definitions for A , B and C ,

Figure 1 Variation of the viscosity (●) of methanol-CO₂ mixtures and the diffusion coefficient (▲) of benzene at 25°C and 170 atm as a function of mixture composition. (Reproduced with permission from Cui and Olesik (1991).)

the optimum velocity, u_{opt} , is described by eqn [3]: C_{stag} (eqn [4]):

$$u_{\text{opt}} \propto \frac{D_m}{\sqrt{f(k')}} \quad [3]$$

$$C_{\text{stag}} = \frac{f(k)}{D_m} \quad [4]$$

The use of enhanced-fluidity mobile phases is expected to increase the diffusion coefficients of the solute and therefore shift u_{opt} to larger values.

For most HPLC separations that involve packed columns containing porous particles and function at linear velocities greater than u_{opt} , the predominant contribution to band dispersion is the diffusion in the stagnant mobile phase inside the porous packing,

k is the retention factor and D_m is the diffusion coefficient of the solute in the mobile phase. Therefore, since solutes in enhanced-fluidity liquid mixtures have significantly higher diffusion coefficients than in the organic solvent, chromatographic band dispersion decreases (as will be illustrated later). In addition to higher diffusion rates in enhanced-fluidity solvents, the addition of the liquefied gas often lowers

Figure 2 Variation in the diffusion coefficient of benzene for: squares, 0.70:30 mol fraction methanol-H₂O; triangles, 0.56:0.24:0.20 mol fraction methanol-H₂O-CO₂; circles, 0.49:0.21:0.30 mol fraction methanol-H₂O-CO₂; diamonds, 0.42:0.18:0.40 mol fraction methanol-H₂O-CO₂ as a function of temperature. (Reproduced with permission from Lee and Olesik (1994).)

Figure 3 Variation of Kamlet-Taft α (●) and β (▼) parameter as a function of mixture composition for methanol-CO₂ mixtures at 25°C and 170 atm. (Reproduced with permission from Olesik (1991).)

the capacity factor of solutes in some liquid chromatographies. Significant improvements in efficiency can result from the combination of the two effects.

The separation time for a chromatographic analysis is proportional to the slope of a plot of H versus u . Therefore the separation time is also shortened when using enhanced-fluidity solvents. Finally, Darcy's law (eqn [5]) shows that the pressure drop across a packed chromatographic column is linearly related to the product of the linear velocity, u , and the mobile-phase viscosity, η :

$$\Delta P = \frac{u\eta\varepsilon L}{B^0} \quad [5]$$

Figure 4 Variation of Kamlet-Taft π^* as a function of mixture composition for methanol-CO₂ mixtures at 25°C and 170 atm. (Reproduced with permission from Cui and Olesik (1991).)

where B^0 is the specific permeability, ΔP is the pressure drop across the column, ε is the interparticle porosity, η is the viscosity and L is the length of the column.

Experimental Methods and Instrumentation

The instrumentation required to do enhanced-fluidity liquid chromatography is very similar to a standard HPLC with two exceptions. Firstly, the components of the mobile phase (liquefied gas and associated liquid) are mixed under pressurized conditions. Therefore two pumps are required to make the mixtures. Either syringe pumps or reciprocating pumps may be used. Pumps that are commonly used for SFC are optimum for pumping the liquefied gases. Secondly, the outlet of the column must be pressurized to maintain single-phase conditions for the mobile-phase mixture at least until after the solutes are detected. Therefore a flow restrictor similar to those used in SFC is used in enhanced-fluidity LC. However, the problems which are often experienced in SFC with restrictor plugging do not occur in enhanced-fluidity LC because phase changes are not occurring in the restrictors and the solvent strength of the enhanced-fluidity liquids is greater than that of commonly used supercritical solvents. Finally, phase diagram information can be used to determine what the minimum operating pressure at the end of the column should be, to ensure that the mobile phase is operating under single-phase conditions. This information for the mixtures described herein is readily available in the literature.

Reversed-Phase Chromatography

When methanol-H₂O-CO₂ mixtures are used in reversed-phase separations with an octadecyl polysiloxane stationary phase, the efficiency of the separation increases significantly compared to the same conditions without the addition of CO₂. For example, the reduced plate height for naphthalene at a reduced velocity of 10 decreased from 11 to 4 for a mobile-phase composition change involving the addition of 0.50 mol fraction CO₂ to a 0.7 : 0.3 mol ratio methanol-H₂O mixture. The addition of 0.5 mol fraction CO₂ to the 0.7 : 0.3 mol ratio methanol-H₂O shortens the analysis time of a separation of polynuclear aromatic hydrocarbons by factors of 2.5 and 8 at linear velocities of 0.15 (reduced velocity = 5) and 0.35 (reduced velocity = 17) cm s⁻¹, respectively, compared to that for the methanol-water mixture at the same linear velocities.

Figure 5 shows the variation in the band dispersion of pyrene using the 0.70 : 0.30 mol ratio methanol-

Figure 5 Variation of plate height with mobile-phase linear velocity for pyrene at 204 atm for different mobile-phase conditions: triangles, 0.70 : 0.30 mol ratio methanol-H₂O at 26°C, $k' = 3.77$; circles, 0.70 : 0.30 mol ratio methanol-H₂O at 60°C, $k' = 2.02$; diamonds, 0.49 : 0.21 : 0.30 mol ratio methanol-H₂O-CO₂ at 26°C, $k' = 1.82$; squares, 0.49 : 0.21 : 0.30 mol ratio methanol-H₂O-CO₂ at 60°C, $k' = 0.92$. (Reproduced with permission from Lee and Olesik (1994).)

H₂O mixture, with 0.30 mol fraction CO₂ added at room temperature and with 0.30 mol fraction CO₂ added at 60°C. As expected, the band dispersion decreased and the optimum linear velocity increased when CO₂ was added to the mobile phase. The increase in temperature also yields substantial gains in efficiency, especially at high linear velocities.

Figure 6 shows the improved separation time which is possible by adding CO₂ and increasing the temperature to 60°C at the same linear velocity for the separation of 16 polynuclear aromatic hydrocarbons. The separation required approximately 40 min with 0.70 : 0.30 methanol-H₂O approximately 15 min when 0.30 mol fraction CO₂ was added and less than 7 min when this mixture was heated to 60°C. However, when 30% CO₂ was present in the mobile phase and the temperature was 60°C, the selectivity of the separation degraded substantially.

Also, due to the low viscosity of the methanol-H₂O-CO₂ multiple columns can be placed in series to increase the overall efficiency of a chromatographic separation. For the same linear velocity, Figure 7 compares the separation of a coal tar sample using one and four ODS columns. Substantial gains in efficiency are obtained by placing the columns in series.

However, the addition of liquefied CO₂ is not optimal to improve the performance of every separation. When CO₂ is mixed with H₂O, carbonic acid is for-

med. The acidic nature of this mobile phase can have a significant impact on the retention factor of ionizable compounds. Also CO₂ and H₂O are not highly miscible at room temperature without the addition of a co-solvent. Even with the addition of co-solvent, the total amount of CO₂ that is miscible in the mixture is controlled by the amount of H₂O present. For example, a 0.70 : 0.30 mol ratio methanol-H₂O mixture is immiscible with more than 0.50 mol fraction CO₂. To eliminate many of these problems, other liquefied gases can also be used to modify the fluidity of the mixture.

Normal-Phase Chromatography

The addition of a liquefied gas is even beneficial when mixed with nonpolar solvents commonly used in normal-phase LC. For example, when 50 mol% CO₂ is combined with 50 mol% hexane, the efficiency increases by at least a factor of 2 across the entire range of linear velocities studied and the mobile phase viscosity also decreases by a factor of approximately 2. However, the addition of proportions of CO₂ greater than 50 mol% causes significant peak asymmetry and decreased efficiency.

Size Exclusion Chromatography

In size exclusion chromatography (SEC), the selectivity of the separation is not affected significantly by the

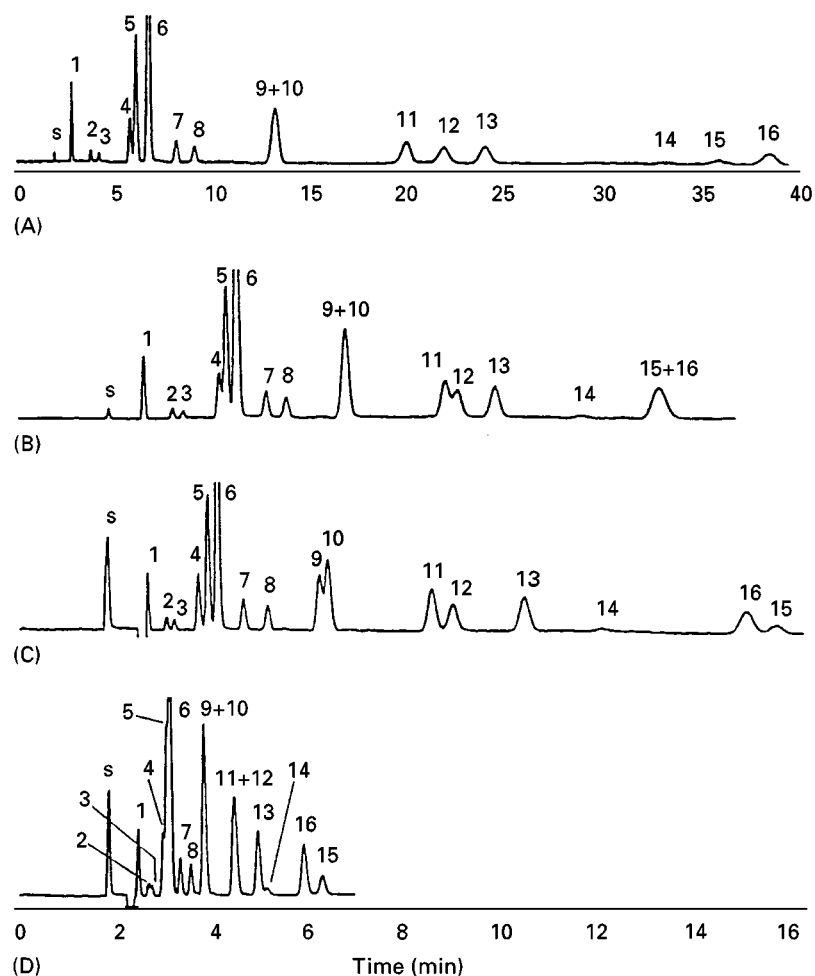

Figure 6 Chromatograms of 16 polynuclear aromatic hydrocarbons at 204 atm for different mobile-phase conditions: (A) 0.70 : 0.30 mol ratio methanol-H₂O at 26°C; (B) 0.70 : 0.30 mol ratio methanol-H₂O at 60°C; (C) 0.49 : 0.21 : 0.30 mol ratio methanol-H₂O-CO₂ at 26°C; (D) 0.49 : 0.21 : 0.30 mol ratio methanol-H₂O-CO₂ at 60°C. 1, Benzene; 2, naphthalene; 3, acenaphthalene; 4, fluorene; 5, phenanthrene; 6, anthracene; 7, fluoranthene; 8, pyrene; 9, benzo[a]anthracene; 10, chrysene; 11, benzo[b]fluoranthene; 12, benzo[k]fluoranthene; 13, benzo[a]pyrene; 14, dibenzo[a,h]anthracene; 15, benzo[ghi]perylene; 16, indeno[1,2,3-cd]pyrene. (Reproduced with permission from Lee and Olesik (1994).)

choice of mobile phase because the separation is based solely on the entropic partitioning of the solute between the bulk mobile phase and the stagnant solvent in the pores. Therefore, efficient separations are highly desirable in SEC. Often, to increase the total efficiency of a separation, analytical columns are connected in series until the maximum pressure of the chromatographic pumping system is approached. SEC is frequently used at elevated temperatures to improve the solubility of high MIC samples and this also lowers the mobile-phase viscosity and allows more columns to be linked together to increase the total efficiency of the separation.

Enhanced-fluidity liquid mixtures can improve the chromatographic performance of SEC without need-

ing to increase the temperature. When CO₂ was added to tetrahydrofuran (THF) for the separation of polystyrene standards, improved efficiency and decreased separation time resulted. For a mobile-phase velocity of approximately 0.8 cm s⁻¹, the reduced plate height for polystyrene (*M_w* 12 600) decreased by a factor of 2 by adding 0.40 mol% CO₂ to the THF. In addition, the 40 mol% CO₂ : 60 mol% THF mixture had a viscosity that was approximately 50% that of pure THF, which resulted in an approximate 50% decrease in the separation time for the separation. However, when greater proportions of CO₂ were added to the THF, the solvent strength diminished significantly, which caused adsorptive interactions to compete with the exclusion mechanism.

Both enhanced-fluidity SEC and high temperature SEC have limits to the scope of their application. Enhanced-fluidity SEC is limited by the solvent strength of the high fluidity mixtures and high temperatures can cause decomposition of the polymer. Therefore the combination of increased temperature and use of enhanced-fluidity SEC might often be the best choice to improve the chromatographic performance in exclusion separations.

By adding 30 mol% CO₂ to THF and increasing the temperature from 24 to 80°C, the slope of a plot of reduced plate height versus linear velocity decreases substantially. For example, with styrene as the solute, the C coefficient in the van Deemter equation decreases to a value that is only 17% of the C value when THF at 24°C is the mobile phase (Figure 8). With such a flat slope, SEC separations can be accomplished at high velocities with minimal loss in efficiency.

Liquid Chromatography at Critical Condition

Liquid chromatography at the critical condition is a separation method that allows the analyst to decide what portion of the molecule will control the separation. For example, at the critical condition for polystyrene polymers, all polystyrene oligomers will elute at the same elution volume, while functionalized polystyrene will be separated based solely on the functionality distribution within the polymer. This method can also be used to make a component of a copolymer chromatographically invisible and then obtain separation based on the other components of the copolymer.

At the critical condition, the change in free energy associated with the transfer of the polymer (in this case, polystyrene) to the stationary phase is zero. That is, at the critical condition, the enthalpic interaction and the entropic interaction of the polymer with

Figure 8 Variation of reduced plate height of styrene using a Betasil silica column with mobile-phase linear velocity using different mobile-phase compositions: diamonds, pure THF at 24°C; circles, 70 : 30 mol% THF-CO₂ at 24°C; triangles, pure THF at 80°C; squares, 70 : 30 mol% THF-CO₂ at 80°C. (Reproduced with permission from Yuan and Olesik (1997b).)

the stationary phase are exactly balanced. This chromatographic condition is typically found by carefully changing the mixture composition used as the mobile phase until this thermodynamic condition is met. This specific composition is sometimes difficult to determine experimentally.

Because the solvent strength of enhanced-fluidity liquid mixtures changes with varying pressure and,

temperature, as well as mixture composition, the critical condition is more readily found using these liquid mixtures than common liquids. **Figure 9** shows a molecular weight calibration plot for polystyrene polymers. With enhanced-fluidity liquid mixtures, by

(Reproduced with permission from Yuan and Olesik (1998a).)

changing the temperature and or pressure, all three modes of separation (size exclusion, critical chromatography and adsorption chromatography) of polystyrene polymers are possible using the same mixture as the mobile phase. Increased efficiency is also beneficial at the critical condition because only the weak interactions of the functionalities or of the other components of a copolymer control the separation. The low viscosity of enhanced-fluidity liquid mixtures allows significantly improved efficiency. Long (2 m) packed capillary columns have been produced that have efficiencies as high as 100 000 theoretical plates. Figure 10 shows an example of the critical condition separation of mono- and dicarboxy-terminated polystyrene polymers separated at the polystyrene backbone with a long packed capillary column.

Use of Alternative Liquefied Gases

While CO₂ was the first liquefied gas used for enhanced-fluidity liquid chromatography, other gases may also be useful to increase the fluidity of a liquid mixture. CO₂ is limited in its applications in that, when it is included in mixtures with water, carbonic acid is produced. Acidic buffer conditions can be generated for the reversed-phase separations but not basic buffers.

For a gas to be useful as a fluidity modifier, the gas must be highly miscible with the organic liquid solvent and have a low viscosity. Fluoroform is an example of a liquified gas that is highly soluble under similar pressure and temperature conditions to CO₂. Accordingly, the efficient separation of basic solutes using basic buffered mobile phases is possible when fluoroform is used to decrease the viscosity of the mobile-phase mixture instead of CO₂. For example, Figure 11 shows a comparison of the separation of some triazine herbicides and a common metabolite, hydroxyatrazine, using 64 : 36 mol% methanol–10 mmol L⁻¹ phosphate buffer (Figure 11A) with 51 : 29 : 20 mol% methanol–10 mmol L⁻¹ phosphate buffer–CO₂ (Figure 11B) and 51 : 29 : 20 mol% methanol–10 mmol L⁻¹ phosphate buffer–fluoroform (Figure 11C) as the mobile phase with the same flow restrictor. The addition of CO₂ clearly causes the co-elution of the more polar solutes. When the chromatogram using the methanol–buffer mixture is compared to that containing the same mole ratio methanol–buffer but with the addition of 0.20 mol fraction fluoroform, use of fluoroform is clearly optimal. The linear velocity and the efficiency increased with the addition of fluoroform. At constant linear velocity, the addition of 20 mol% fluoroform to the methanol–buffer solution increased the efficiency by approximately 30%.

Other Separations Using Enhanced-Fluidity Liquid Mixtures

The extraction of polar pollutants from very adsorptive matrices is a difficult task. A large range of polar pollutants can be effectively removed from adsorptive matrices such as dust and fly ash, by using enhanced-fluidity liquid mixtures. Solutes as polar as phenols,

triazine herbicides, and as large as 3–4 ring polynuclear aromatic hydrocarbons are effectively removed using enhanced-fluidity liquid mixtures, such as methanol–H₂O–CO₂ and methanol–H₂O and are superior to the use of other standard methods such as Soxhlet extraction.

Conclusions

Improved performance has been observed using enhanced-fluidity liquid mobile phases in every type of liquid chromatography studied to date. As mentioned earlier, typically as much as 50 mol% liquefied gas can be added to a polar solvent while still maintaining much of the solvent strength of the original organic solvent. As the solvent strength of the mixture decreases for mixtures containing more than 50 mol% liquefied gas, the chromatographic performance decreases. Extraction techniques for highly polar substances that would otherwise be very difficult to extract have been developed using enhanced-fluidity liquid mobile phases. The use of enhanced-fluidity liquids as mobile phases has also made viable a powerful technique termed critical chromatography. This separation method allows careful characterization of functionality distributions in polymers and oligomer distributions in copolymers. The precise control of solvent strength that is possible with enhanced-fluidity liquids will allow critical chromatography to be more thoroughly studied.

Reversed-phase liquid chromatography is presently the most commonly used HPLC method. pH variation is often used to control retention in reversed-phase HPLC. While the use of enhanced-fluidity mixtures significantly improves the chromatographic performance in reversed-phase HPLC, more information is needed on pH control in these mixtures to evaluate the potential of enhanced-fluidity liquid mixtures.

Chiral chromatography is another area of separation science where enhanced-fluidity liquid mixtures may find applications in the future. Increasingly, SFC is under consideration for chiral separations. However, solvent strength often limits the utility of SFC. Enhanced-fluidity liquid mixtures have high solvent strength and therefore may be applicable to separations that SFC cannot handle.

Historical Development

Tswett's papers on chromatography were published at the beginning of the 20th century but there was little interest in the technique for several decades. It was not until the 1930s that a growing number of researchers used liquid chromatography (LC) in open columns for the successful separation of complex mixtures of natural compounds, and it was only in the 1970s that LC found widespread use in its instrumentalized form. Over this time it developed:

- from a simple set-up to sophisticated instrumentation with computer assistance
- from the separation of coloured compounds which did not need an instrument for detection to an impressive variety of detectors which allow quantitation of analytes in the picomol range and lower
- from adsorption chromatography as the single option to a large number of varied separation principles (adsorption, reversed-phase, polar bonded phase, ion exchange, enantioselective, size exclusion and affinity chromatography)
- from trial-and-error to a deep understanding of theory, separation mechanisms and method development
- from open-column separations to high performance, closed-column chromatography
- from nonacceptance by the greatest scientists of the time to a method of the utmost importance.

It is difficult to name the most important participants in this development; exceptions are Martin and Synge, who published a paper in 1941 that can be looked upon as the beginning of modern chromatography. A large number of other scientists were responsible for various improvements in LC: **Table 1** lists the most important historical papers in the development of the technique.

The Beginning

Open-column LC was invented by Michael (Mikhail) Semenovich Tswett (1872–1919) at the beginning of

the 20th century and he was responsible for naming the method. Paper, thin-layer, closed-column liquid and gas chromatography were later invented by other scientists who varied the method set-up described by Tswett.

The father of chromatography was not a chemist but a botanist. Although born in Asti, Italy, and educated in Geneva, Switzerland, he was a Russian national. In 1896 he obtained a PhD from the University of Geneva. Later, when he was an assistant professor at the University of Warsaw, Poland, he needed a method to isolate plant pigments in pure form. At that time the standard technique for this purpose was the partition of plant extracts between immiscible organic solvents. However, Tswett was also interested in the problem of how the pigments are fixed, i.e. adsorbed, within the plant cell. He carried out numerous experiments with adsorbents and tested

more than 100 different powdered materials. Finally he found that inulin, sucrose and calcium carbonate were best suited for the separation of the pigments of green leaves – chlorophylls (two compounds) and xanthophylls.

Unfortunately the new method was only described in lectures, in a paper in a German botanical journal (1906) and in a book in the Russian language (1910). It is obvious that most chemists did not read either botanical journals or a Russian book published in Warsaw. Moreover, when reading these texts today, many details of the experimental set-up are missing. These facts, together with the outbreak of World War I in 1914 and Tswett's untimely death at the age of 47 in 1919, hindered the acceptance of the new method.

Tswett mainly used small glass columns of 2–3 mm diameter packed with adsorbent to a height of c. 30 mm. The plant extract was applied on top of the column and transported into the packing by a solvent – the mobile phase – which was added on top and sucked through the adsorbent by a slight vacuum or forced through with a slight pressure. The best eluents were found to be benzene and carbon disulfide; solvent mixtures and even gradients could also be

used. Several columns could be used in parallel (**Figure 1**).

Tswett did not publish more than three 'chromatograms'; one is shown in **Figure 2**. Experimental details of all these drawings are missing. The pigments were not eluted but the whole packing was pushed out of the glass tubing and the different zones were then cut apart with a knife. The pigments were extracted from the adsorbent by an appropriate solvent and identified by UV spectroscopy (which was a tedious and time-consuming method). **Figure 3** makes clear how similar the structures of chlorophylls a and b are and, from our current perspective, we get the impression that Tswett was a very skilled experimenter. It was difficult to reproduce his separations using only his descriptions.

The First Followers

A small handful of researchers used chromatography with great success despite the obstacles outlined above: Gottfried Kränzlin, Charles Dhéré and co-workers, and Leroy Sheldon Palmer. They were all able to isolate pure compounds from natural mixtures.

Figure 2 Separation of plant pigments as obtained by Tswett. (Redrawn after Tswett, 1906; see Table 1.)

Figure 3 The structures of the chlorophylls separated by Tswett. Chlorophyll a: R = CH₃; chlorophyll b: R = CHO.

Kränzlin, at the Friedrich-Wilhelms University of Berlin, Germany, used Tswett's method in his PhD thesis work in the years 1906 and 1907 – just after Tswett's paper had been published. In a semiquantitative manner he determined the content of chlorophylls and carotenes in various plants from the width of the chromatographic bands. Dhéré was a professor of physiology at the University of Fribourg, Switzerland. In two PhD theses carried out under his guidance, chromatography was used to solve analytical problems: the spectroscopic investigation of the chlorophylls (Wladyslaw de Rogowski, 1914) and the isolation and characterization of invertebrate pigments (Guglielmo Vegezzi, 1916). Palmer, an agricultural chemist, used chromatography for his PhD thesis work at the University of Missouri, USA, in 1909–13. He investigated the pigment content in cattle food, i.e. grass, hay, and carrots, as well as in milk and butter. He proved that the carotene in cow's milk comes from the food plants and is not synthesized by the animal.

The work of these pioneers had only a minor influence on the later development of chromatography, perhaps because they were not chemists (or pure chemists) but were engaged in related fields. The great authorities of natural compound chemistry of the 1910s and later, most of all, the Nobel prize winner Richard Willstätter, were sceptical about the usefulness of chromatography.

The Renaissance

In fact, Willstätter had first-hand knowledge of chromatography because he owned a German translation of Tswett's book (the translator is unknown). Later the translated text came into the possession of Richard Kuhn, a professor of chemistry at the Kaiser Wilhelm Institute for Medical Research at Heidelberg, Germany; Kuhn was a former student of Willstätter. In 1930, Edgar Lederer joined Kuhn as a postdoctoral fellow. His task was to separate xanthophyll

(today called lutein) and zeaxanthin (Figure 4), and he was able to solve this problem after reading Tswett's book. Lederer used what we would call today preparative columns – glass tubes with a diameter of 7 cm. The results were published in three papers which appeared in leading German scientific journals in 1931. These articles mark the breakthrough and acceptance of chromatography. The method was successfully used in the laboratories of Nobel prize-winners Paul Karrer and Leopold Ruzicka (who received the award in 1937 and 1939, respectively; Kuhn was awarded it in 1938). All these scientists were active in the isolation and structure elucidation of natural compounds, and chromatography was an invaluable help to them.

The main problem in these years was how to find suitable stationary phases. Systematic tests and good luck were necessary to establish adsorbents such as alumina, magnesia and silica. Some researchers began to elute the chromatographic bands from the column instead of cutting the packing; however, it is not clear who used this technique first. It was proved that chromatography can be used on a large scale; Winterstein was able to obtain gram quantities of chlorophylls by using 12.5 cm i.d. columns.

The first application of chromatography to compounds other than organic molecules was done by Georg-Maria Schwab in Munich, Germany. In 1937 he separated inorganic cations on alumina. The first enantioselective separation was performed by Geoffrey M. Henderson and H. Gordon Rule, also in 1937. They were able to partially resolve (*R,S*)-phenylene-bis(iminocamphor) on lactose with petroleum-benzene 8 : 1 as the mobile phase.

From Empirism to Science

In 1940, Archer J. P. Martin and Richard L. M. Synge, two researchers at the Wool Industries Research Association in Leeds, England, were trying to separate the amino acids of wool proteins. They

Figure 4 The structures of the carotenes separated by Lederer. (A) Lutein (xanthophyll); (B) zeaxanthin.

attempted to solve the problem by countercurrent extraction of the acetyl derivatives with water and chloroform. This process was time-consuming (one run took a week), tedious and required large volumes of solvents. With ingenuity they came upon a completely different procedure; they immobilized the water phase on silica, packed this material into columns and used the chloroform (with 1% *n*-butanol) as the mobile phase. Although this was chromatography, the technique was different to what had been done previously. It was not based on adsorption but on the partition between two liquid phases (water being the stationary phase). Martin and Synge had invented liquid-liquid partition chromatography.

In addition to the practical applications of liquid-liquid partition chromatography, Martin and Synge's paper also included:

- a theory of the chromatographic separation process which used the theoretical plate as a hypothetical compartment within the column where the solutes are equilibrated between the mobile and stationary phase (this concept was taken from the theory of distillation)
- the statement that a chromatographic process is governed by the diffusion coefficient of the analyte, which leads to specific problems for the separation of large molecules such as proteins
- the insight that there is an optimum flow rate for any chromatographic separation
- the prediction that the finer the particles of the stationary phase, the more efficient the column (this led to high performance liquid chromatography (HPLC) some 25–30 years later)
- the proposal that the mobile phase could also be a gas (this led to gas chromatography (GC), which was first successfully pursued by James and Martin some 10 years later).

In 1952 Martin and Synge were given the Nobel prize for their truly remarkable prescience.

The plate theory of chromatography was defined in the 1950s by Eugen Glueckauf (who worked for the UK Atomic Energy Authority) and others. It became clear how the separation performance can be influenced, i.e. which prerequisites are necessary for efficient chromatography. The prediction of Martin and Synge was quantified by Calvin Giddings: it would be necessary to use stationary-phase packings with particle diameters of 10 μm or less in order to get faster and better LC separations. In 1955, Jan J. van Deemter presented a rate theory approach to describe the chromatographic process and discussed the influence of mobile-phase velocity on the height of

a theoretical plate to give relationships known today as van Deemter curves. They show that there is an optimum mobile-phase flow rate for separations performed by gas, liquid or supercritical fluid chromatography.

A fruitful concept for the judgement and comparison of LC separations was introduced in 1977 by John H. Knox with reduced (dimensionless) expressions for theoretical plate height, mobile-phase velocity, pressure drop and overall efficiency. An excellent column should have a reduced plate height of not higher than 3, irrespective of its size, and the reduced flow velocity must not be smaller than 3, irrespective of the chemical natures of the phase system and the analytes.

Towards HPLC

The pre-HPLC era can be defined as the decades when particles of 20 μm and larger were used as stationary phases. High pressure was not necessary and the separations were usually performed with gravity flow or with moderate vacuum at the column outlet, i.e. without a pump. Hindered first by World War II and later, to a certain extent, by the impressive rise of GC, progress was slow but steady.

In the 1930s, the first ion exchange resins were synthesized and became commercially available in the next decade. They could be used not only for batch processes (e.g. desalting) but also as stationary phases, thus opening a new separation principle to LC. During World War II the ability to separate and identify the rare earth ions was of utmost importance in the research activities which led to the construction of nuclear bombs.

The first reversed-phase separations were performed in 1950 by Martin and Howard with a stationary phase of silylated kieselguhr and a

Figure 5 Size exclusion chromatogram of dextran (mol wt 20 000), dextran (mol wt 1000) and glucose as obtained by Porath and Flodin. Column: 36.5 \times 4.0 cm i.d.; stationary phase: dextran gel 100–200 mesh; mobile phase: water, 110 mL h⁻¹. (Reproduced from Porath and Flodin, 1959; see Table 1.)

Figure 6 Separation of amino acids as obtained by Moore, Sparkman and Stein. Column: 150 × 0.9 cm i.d.; stationary phase: Amberlite Type III cation exchanger 400–600 mesh; mobile phase: citrate buffer pH 3.25 and pH 4.25, 12 mL h⁻¹. (Reproduced from Moore *et al.*, 1958; see Table 1.)

water-methanol-*n*-octane mobile phase. This system allowed the separation of fatty acids.

At Uppsala University, Sweden, Arne Tiselius introduced new chromatographic and electrophoretic techniques into biochemical research and invented flow-through refractive index detectors. (Previously, the effluent from a column had been collected as individual fractions which were analysed offline.) The first application of gradient elution chromatography was also made in the laboratories of Tiselius: mixtures of oligosaccharides were separated by a continuous increase of the ethanol content of the aqueous mobile phase. Also in Uppsala, size exclusion chromatography (as gel filtration with an aqueous mobile phase) was invented by Per Flodin and Jerker O. Porath (Figure 5). The stationary phase with well-defined pores was a cross-linked dextran.

Gel permeation chromatography, i.e. size exclusion in organic solvents, was introduced in 1964 with cross-linked polystyrenes by John C. Moore. For the convenient use of this analytical method an instrument was also built. In retrospect we can say that this was the first liquid chromatograph, in that it included all the necessary parts, from the pump to a refractive index detector. Several years before, in 1958, a specialized instrument, the automated amino acid analyser, had been introduced by Stanford Moore and William H. Stein. Although the separation of a complex mixture (with up to 50 amino acids and related compounds!) took several days (Figure 6), this analytical tool was of utmost value for biochemical research. It was a real breakthrough and a revolution. The separation was based on a polystyrene-type cation exchanger run with citrate or acetate buffers at elevated temperature.

Affinity chromatography, a highly selective bio-analytical technique, goes back to Jerker O. Porath and to Meir Wilcheck in 1967–68. This powerful method can be used for the isolation of proteins (e.g. insulin) or the quantitative analysis of bioactive compounds (e.g. aflatoxins).

High Performance Liquid Chromatography

The term HPLC is appropriate for separations of any size (from microanalytical to preparative) if the particles of the stationary phase are not larger than about 10 µm and if the reduced plate height (after Knox) is not larger than 5. This means that the pressure which is necessary in order to force the mobile phase through the column is a parameter of minor importance (the P in HPLC meant pressure when the abbreviation was first coined). It was a long way from pressure to performance with a wealth of technical improvements. Two obstacles needed to be overcome: it was not easy to pack columns with 5 µm particles, and the construction of pumps that can deliver a constant, pulse-free flow as low as e.g. 1 mL min⁻¹ at pressures up to 300 bar was demanding. Today we can choose from hundreds of packed column types and dozens of pumps.

Stimulated by the successful amino acid analyser and by the need of a separation method for molecules not suitable for GC, research activities towards an improved, instrumentalized LC began in the late 1960s. Although the available instruments were less sophisticated and less convenient than those available today and despite the fact that most users had to pack their own columns, it soon became clear that HPLC is

Figure 7 Separation of *(R,S)*-*n*-dodecyl-2,4-dinitrophenyl sulfoxide on a trifluoroantrhyryl ethanol chiral stationary phase as obtained by Pirkle and House. Column: 25.4 × 1 cm i.d.; mobile phase: hexane–2-propanol 4 : 1. (Reproduced with permission from Pirkle WH and House DW (1979) *Journal of Organic Chemistry* 44: 1957.)

a useful method for almost any type of sample. Much of the success of the new method was due to a number of excellent books which soon appeared; the most popular one was *Introduction to Modern Liquid Chromatography* by Lloyd R. Snyder and Jack J. Kirkland (first edition 1974), from which the first generation of users learnt the technique. In 1973, the first International Symposium on Column Liquid Chromatography took place in Interlaken, Switzerland.

Besides the techniques still in use today (adsorption, reversed-phase, ion exchange, size exclusion and affinity chromatography), in the early years of HPLC liquid–liquid partition chromatography was also used, following Martin and Synge's first paper. The stationary phase consisted of a liquid film held in place by a support, i.e. a special type of adsorbent. Although such a separation system can be highly

selective, it was inconvenient and temperature-sensitive. Classical liquid–liquid chromatography was abandoned with the rise of chemically bonded stationary phases of almost any polarity and selectivity.

The most important bonded phases are the C_8 and C_{18} reversed phases which are used with an aqueous eluent. The separation principle, first described by Martin and Howard (see above) gained in importance mainly due to the activities of Jack J. Kirkland and Istvan Halász. Today approximately half of all HPLC separations are performed in the reversed-phase mode. New developments in the field of stationary phases are nonporous particles of about 1 μm size; perfusive particles with large throughpores which allow the mobile phase to flow (not diffuse) through the body of the particle; and monolithic, rod-type chromatographic beds which are not built up from

particles but consist of one single, porous piece of stationary phase. All these concepts allow separation speed to increase markedly.

An important class of stationary phases which is now in widespread use are the chiral phases. Enantioselective chromatography can also be done with chiral additives in the mobile phase or with pre-column derivatization to diastereomers but the approach using chiral stationary phases (CSPs) was the most fruitful. Although not the first CSP, the trifluoroanthyrylethanol phase by William H. Pirkle opened the door to this new analytical field in 1979 (Figure 7). A large number of research groups found numerous other CSPs, including the cellulose and amylose derivatives of Yoshio Okamoto.

The introduction of materials for the separation of proteins and other biomolecules by Fred E. Regnier in 1976 and by William S. Hancock and Milton T. W. Hearn in 1978 marked an important breakthrough. The rise of industrial biotechnology was in fact only possible as HPLC was capable of identifying proteins or peptides exprimed by mutants, i.e. of guaranteeing the true identity of the isolated product (Figure 8).

Snyder's work on the interaction between stationary and mobile phase led to a better understanding of adsorption chromatography and to a scientific classification of solvents with regard to their dipole, proton donor and proton acceptor properties. Such classification is also important for reversed-phase separations and gives a sound background to the choice of methanol, acetonitrile or tetrahydrofuran in addition

to water or buffer as mobile-phase components. Several computer simulation programs have been developed which allow the prediction of separations based on the chemical structures of the analytes and to optimize the separations. It has been recognized how important temperature can be for most HPLC separations; therefore this parameter should be studied and optimized, too. High temperatures, even above the boiling point of the mobile phase, lead to fast separations; however, not all stationary phases are suited to such conditions, and a pressure restrictor at the detector outlet is necessary in order to prevent bubble formation in the cell.

With regard to instrumentation, continuous improvement in all parts of the HPLC system has taken place and is still going on. This concerns degassing systems, pumps, tubing, fittings, injection valves, autosamplers, columns (e.g. the cartridge principle), detectors and data handling. Authorities now demand that analyses are performed in accordance with Good Laboratory Practice or similar guidelines, therefore all aspects of the analysis, including data acquisition by computers and their manipulation by personnel, must be regulated. Concerning detectors, the refractive index principle was invented decades ago and UV and fluorescence detection were rather obvious. The diode array detector (Hewlett-Packard, 1979) was not obvious but it revolutionized the possibilities for analyte identification and peak purity judgement by UV/Vis spectroscopy. Of the less frequently used detectors, the electrochemical detector is

Figure 8 Separation of the tryptic hydrolysate of tissue-type plasminogen activator as obtained by Garnick, Solli and Papa. Top: normal protein with arginine at position 275; bottom: erroneous peptide with glutamic acid at position 275. Stationary phase: Nova Pak C18, 5 μm ; mobile phase: phosphate buffer pH 2.8/acetonitrile, step gradient, 1 mL min⁻¹; detector: UV 210 nm. an important one (Peter T. Kissinger, *c.* 1975): it can be used for analytes with readily oxidizable or reducible functional groups. An alternative to refractive index detection is the light-scattering detector for nonvolatile analytes. This instrument is able to detect all types of molecules irrespective of the presence or lack of functional groups; it does not respond to changes in eluent composition or temperature in the way that the refractive index detector does. LC-mass spectrometry (LC-MS) is no longer in its infancy and could become one of the most important detectors, even for routine analyses. LC-nuclear magnetic resonance (LC-NMR) has been developed into an excellent tool for structure elucidation. Depending on analyte concentration, NMR spectra can be obtained online or offline after storage of the relevant chromatographic peaks in loops.

Despite new techniques such as capillary electrophoresis, HPLC continues to be probably the most important analytical method, with more 100 000 instruments in daily use worldwide.

The Instrumental Set-Up

Modern high performance liquid chromatography (HPLC) uses high pressure to force the mobile phase and an analyte through a closed column packed with micron-size particles, which constitute the stationary phase. HPLC instrumentation is made up typically of nine basic components: mobile phase/solvent reservoir; solvent delivery system; sample introduction device; column; post-column apparatus; detector; data collection and output system; post-detector

eluent processing; and connective tubing and fittings. All components except for the post-column apparatus are essential to performing HPLC. **Figure 1** shows a schematic diagram of a generic high performance liquid chromatography system.

Mobile-Phase Reservoir

The mobile-phase reservoir can be any clean, inert container. It usually contains from 0.5 to 2 L of solvent, and it should have a cap that allows for a tubing inlet line, which feeds mobile phase to the solvent-delivery system. The cap also serves to keep out dust, reduce solvent evaporation, allow for pressurization of the bottle, offer ports for additional inlet lines, and sparging (i.e. dispersing He or Ar into the

Figure 1 Generic HPLC system.

mobile phase to remove dissolved air). All mobile phases/solvents should be freshly filtered and preferably degassed. Online degassers, which are primarily used to remove small gas bubbles and reduce the amount of dissolved air, are now popular additions to many HPLC systems, and they eliminate the need to degas mobile phase offline. An additional filter is often placed at the end of the mobile-phase inlet line to remove any precipitants that may form in the mobile phase during its use. Sparging control and the ability to blanket the solvents with inert gases is highly recommended to eliminate carbonate formation in alkaline solvents and to maintain extremely low levels of dissolved oxygen, when performing electrochemical or fluorescence detection.

Solvent-Delivery System

The high-pressure pump can operate at pressures from 500 to 5000 psi. The purpose of the pump is to deliver a precise, accurate, reproducible, constant, and pulse-free flow of mobile phase to the column. Three major classes of HPLC pumps are currently in use: constant-pressure pumps; syringe-based or displacement pumps; and constant flow pumps. Neither constant pressure or syringe-based pumps are easily adapted to gradient solvent delivery; hence, constant-flow pumps are by far the most common.

The majority of commercial high-pressure pumps available today are designed around a simple recip-

rocating piston pump. The rotational energy of a motor is transferred into the reciprocal movement of the piston by an eccentric cam or gear. The piston is driven in and out of a solvent chamber in the pump head, which typically has a volume of 10 to 100 μ L. A pair of check valves control the direction of flow through the pump head. A piston seal keeps the mobile phase from leaking out of the pump head. On the intake stroke, the piston is withdrawn from the pump head, creating a low-pressure zone. The low pressure causes the inlet check valve (i.e. from the mobile-phase reservoir) to open and the outlet check valve (i.e. delivery to the column) to close, allowing the mobile phase to fill the pump head. On the delivery stroke, the piston moves into the solvent chamber, which increases the pressure. The high pressure closes the inlet check valve and opens the outlet check valve, allowing the mobile phase to flow to the column. In a single-head reciprocating pump, the solvent chamber is delivering mobile phase to the column only half the time. The other half of the time it is being used to fill the solvent chamber. With a twin-head reciprocating pump, two pump heads operate simultaneously but at 180° out of phase with each other. As a result, mobile phase flows to the column 100% of the time. The twin-head design gives essentially pulseless flow as compared to the single-head design.

Many separations can be done isocratically, which means that solvent composition being delivered to the

column is not changing in composition over the course of the separation. For more complex separations, gradient elution is required. Most commonly, gradient elution is performed by altering the proportion of the eluents over the course of the separation. In doing so, the early eluting compounds remain well resolved, while the more highly retained compounds elute quicker. Gradient elution is simply the programming, or changing of the solvent strength over the course of a separation. A gradient can be linear, convex, concave, stepped, or a complex sequence of each to achieve the desired separation. Computer-controlled pumping is required to generate a gradient flow. Three major approaches are used to produce a gradient flow: (i) controlled amounts of each eluent (up to four may be used) are metered into a mixing chamber before reaching the high-pressure pump; (ii) a proportioning valve, which is controlled by a microprocessor, regulates the amount of up to four eluents and the eluent mixture is sent to the high-pressure pump; and (iii) the outputs of multiple high-pressure pumps, which are controlled individually by a programming device, are mixed together in a high-pressure mixing chamber after the pump. Approaches (i) and (ii) are known as low-pressure mixing, and approach (iii) is high-pressure mixing. Low-pressure mixing is less expensive than high-pressure mixing since only one high-pressure pump is used versus the two or more required for high-pressure mixing, and the maintenance of one pump is much easier than the maintenance of two or more pumps. The main problem with low-pressure mixing is that it is more susceptible to bubble formation because the solvents are being mixed at atmospheric pressure. Hence, the common use of online degassers.

Sample-Introduction Device

In many instances, the limiting factor in the precision of an HPLC system lies in the reproducibility of the sample-introduction system. The sample-introduction device, also known as a 'sample injector', is used to introduce the sample into the HPLC system without depressurizing it. The most widely used method of sample injection is based upon a sample loop that can be placed in and out of the mobile phase flow path by merely switching a valve (Figure 2). When the valve is in the load position, the sample loop is filled at atmospheric pressure. Sample sizes often range from 5 to 500 μL . For best results, an excess of sample (i.e. two to five times the injection volume) is flushed through the loop to ensure that no trace of the previous sample remains. By turning the valve from the load to the inject position, the sample loop is connected to the high-pressure mobile-phase stream and the sample is then carried to the column.

Figure 2 Generic high-pressure injection valve shown in the load and inject positions.

The valve-based sample-introduction system is easily automated using simple robotic technology. The use of auto-injectors not only improves injection reproducibility, but they allow for the continuous processing of numerous (i.e. tens to thousands) of samples at a time. Auto-injectors have also been used for the implementation of pre-column derivatization protocols, especially for amino acid analyses. Pre-column derivatization is used to improve the chromatographic and/or detection properties of analytes.

Column

The column is the part of the HPLC in which the separation occurs. HPLC columns are mainly constructed from smooth-bore stainless-steel tubing due to the high-pressure aspects of HPLC. Nowadays columns are sometimes constructed from heavy-walled glass, titanium, or plastic (e.g. PEEK®) to offer the analyst better performance for particular analytes. Common dimensions for analytical-scale

columns are in the range of 10 to 30 cm long and 4 to 10 mm inner diameter. The common particle sizes of packings are 3, 5, and 10 μm . Columns of these dimensions often have efficiencies of 40 000 to 60 000 plates per metre. The current trend has been the use of higher performance, high-speed columns, which have smaller dimensions than those described. Such columns have efficiencies of 100 000 plates per metre and have the advantage of speed and minimal solvent consumption. Hundreds of packed columns in differing size and packing material are available from numerous manufacturers.

It is important to read the manufacturers' literature relating to the maintenance, handling, and limitations of the column (e.g. silica-based columns are only compatible with pH values from 2 to 7). In addition to chemical limitations of the packing material, columns are easily degraded by the irreversible adsorption of impurities from samples and solvents. Hence, a small guard column is often used to protect the integrity of the analytical column, which is much more expensive. Also, for analytes, which may contain particulates, an inline filter can be placed between the injector and guard column. It should be noted that with the addition of each component after the injector, the efficiency of the separation is degraded. Hence, judicious use of inline devices is necessary.

For many applications, close control of column temperature is not necessary and HPLC separations are performed under ambient conditions. However, temperature control can enhance chromatographic reproducibility and afford opportunities to improve separation efficiency. Modern instruments can be equipped with column heaters/ovens that control column temperature to a few tenths of a degree from near ambient to 150°C.

Post-Column Apparatus

If post-column modification of the mobile phase or analyte is required, then the system will have a post-column apparatus in the flow path. Modification of the mobile phase (e.g. addition of buffers, changing the pH, and solvent strength) may be needed to enhance the compatibility of the mobile phase with the detector, while post-column derivatization of the analyte may be needed to improve the detection properties of the analytes after their separation. In either case, a post-column addition system consists simply of a reagent-delivery pump, a mixing-tee, and a mixing coil. Typically, a pressurized reservoir is commonly used to deliver a pulseless flow of the reagent. The vessel is usually fitted with a check valve to prevent reagent back-up. The major drawback of using a pressure-based delivery system is that it can-

not handle a great deal of system back-pressure. Hence, close attention must be paid to the minimization of post-column back-pressure sources. Any single-piston pump, even with extensive pulse dampening, is usually inadequate for high-sensitivity work.

Delivery of the post-column reagent to the chromatographic eluent flow is accomplished via a mixing tee. The mixing tee should be a low dead-volume fitting. Probably the most crucial component in the post-column system is the mixing coil, which connects the mixing tee to the detector. It is essential that the mixing coil produces a homogeneous solution in the most efficient manner, in other words, with minimal band-broadening. The best mixing is obtained with a woven/knitted reaction coil. The three-dimensional weave achieves efficient mixing and effectively reduces band-broadening effects by preventing laminar flow patterns. In addition, their open-tubular nature produces less back-pressure than packed-bed reactors, and woven reactors are easy to make using commercially available Teflon® tubing.

Detector

By passing the column effluent through the detector, some chemical or physical property of the analyte is transduced to an electrical signal, and the solutes are monitored as they are eluted from the column. The electrical signal, which can be amplified and manipulated by suitable electronics, is proportional to the level of some property of the mobile phase or solutes.

HPLC detectors are classified as either bulk-property detectors, which respond to a bulk property of the eluent such as refractive index or conductivity, or solute-property detectors, which respond to some property of the analyte such as UV absorbance. In either case, the response of the detector is modulated by the presence and amount of the analyte. Solute property detectors tend to be more sensitive than bulk property detectors (in the order of 1000 times or more).

Ideal characteristics of an HPLC detector are high sensitivity, good stability, linearity, short response time, reliability, non-destructiveness, ease of use, and low dead volume. Many types of analytical techniques have been applied to HPLC with varying degrees of success. It has been estimated that HPLC detection is divided as follows: 70% by UV absorption, 15% by fluorescence, 5% by refractive index, 5% by electrochemical methods, and 5% by other measurements. Table 1 lists some of the common HPLC detectors and their relevant properties. Only a brief review of the most common detectors is presented here.

Table 1 Performance characteristics of common HPLC detectors

Parameter	Detector				
	UV/vis absorption	Fluorescence	Electrochemical	Conductivity	Refractive index
Classification	Solute property	Solute property	Solute property	Bulk property	Bulk property
Response	Selective	Selective	Selective	Selective	Universal
Sensitivity	Nanogram	Picogram	Picogram	Nanogram	Microgram
Gradient compatibility	Yes	Yes	Limited	Yes (suppressed) No (nonsuppressed)	No
Flow sensitivity	No	No	Yes	Yes	Yes
Temperature sensitivity	No	No	Yes	Yes	Yes

UV/vis absorbance detectors In UV/vis detectors, the mobile phase is passed through a small flow cell, where the radiation beam of a UV/vis photometer or spectrophotometer is located. As a UV-absorbing solute passes through the flow cell, a signal is generated that is proportional to the solute concentration. Only UV-absorbing compounds, such as alkenes, aromatics, and compounds that have multiple bonds between C and O, N, or S are detected. The mobile-phase components should be selected carefully so that they absorb little or no radiation. Absorption of radiation is a function of concentration, c , as described by the Beer–Lambert law: $A = \epsilon bc$, where A absorbance, ϵ = molar extinction coefficient, and b = flow cell path length.

Three types of absorbance detectors are available: fixed wavelength; variable wavelength; and photodiode array. A fixed-wavelength detector uses a light source that emits maximum light intensity at one or several discrete wavelengths (e.g. 254, 280, and 365 nm for a mercury lamp) that are isolated by appropriate filters. A fixed-wavelength detector is the most sensitive and least expensive of the three. A variable-wavelength detector uses a relatively wide bandpass UV/vis spectrophotometer, and has the advantage of wavelength-selection flexibility. It is also more expensive than the fixed-wavelength detector. In order to generate a real-time spectrum for each peak as it is eluted, a photodiode array is used. Comparison of spectra generated chromatographically with a known spectrum is useful for solute identification. In addition, software has been designed to evaluate peak purity with diode array-generated data. The major disadvantage with scanning-wavelength technology is a loss in sensitivity.

Fluorescence detectors Fluorescent detectors exploit the ability of a compound to fluoresce upon irradiation. The emitted light, which is detected at right angles to the irradiation beam to minimize background noise, is then detected similarly to that of the

UV/vis detector. The major advantage of a fluorescent detector is selectivity and sensitivity for fluorescent solutes. Unfortunately, relatively few solutes fluoresce naturally, and analytes of interest must often be derivatized with a fluorescent entity. Because both the excitation and emission wavelengths can be varied, the detector can be made highly selective.

Electrochemical detectors Electrochemical detectors measure the current associated with the oxidation or reduction of solutes as they are eluted from the column. The suitability of electrochemical detection depends on the redox characteristics of the solute molecules in the environment of the mobile phase. Electrochemical detectors have the advantages of high sensitivity, high selectivity, and wide linear range. Most naturally occurring electroactive compounds have an aromatic substituent (e.g. catechols, quinines, and aryl amines). Polar aliphatic compounds (e.g. carbohydrates, amines, and thio compounds) can also be detected directly using pulsed electrochemical detection (PED). PED exploits electrocatalytic detection at noble metal electrodes by combining amperometric detection with pulsed potential cleaning to maintain uniform electrode activity.

Conductivity detectors Conductivity detectors are used primarily to detect ions in conjunction with ion chromatography (IC). This type of detector monitors the ability of the eluent to conduct electricity. In non-suppressed ion chromatography, the conductivity of the eluent is minimized via the careful selection of reagents and control of their concentration. Under these conditions, charged analyte ions are more conductive than the eluent and a signal is generated as they are pumped through the detector. In suppressed ion chromatography, the response of the background is neutralized using a post-column suppressor (e.g. eluent hydroxide ions in anion-exchange chromatography and eluent hydrogen ions in cation-exchange

chromatography are neutralized to water). Under these conditions, only the charged analyte ions are detected. Suppressed IC inherently, and in practice, has superior detection limits as compared to non-suppressed IC, despite having a larger dead volume.

Refractive index (RI) detectors Refractive index detectors monitor the difference in refractive index between the column eluent containing analyte and a reference stream containing mobile phase only. These detectors are the closest to universal detectors in HPLC because any solute can be detected as long as its refractive index is different from that of the mobile phase. Unfortunately, RI detection is limited by a number of significant drawbacks. The sensitivity of RI detection (Table 1) is poor owing to the small differences in the absolute refractive indices of many substances commonly analysed by HPLC. RI detection is sensitive to both temperature and pressure changes, and, as a consequence, strict temperature control of the detector and pulseless flow are mandatory. Since RI is a bulk property detector, it is sensitive to changes in the mobile-phase composition, as well as analyte concentration, and it is not amenable to gradient elution. Gradient elution can be performed with RI if the detector is configured with a working and a reference column and two flowing liquid streams – this is easier said than done.

Mass spectrometer Owing to innovations in LC-mass spectrometry (MS) interfacing, MS has become a very important HPLC detector because of its ability to generate structural and molecular weight information about the eluted solutes. The combination of HPLC and mass spectrometry allows for both separation and identification in the same step, an advantage few of the other detectors provide. Two major problems must be addressed when interfacing MS with HPLC. First, the flow rate in HPLC with conventional 4.6 mm i.d. columns is about 1 mL min^{-1} , which is much larger than the flow that can be taken by the conventional mass spectrometer vacuum systems. Second, MS has difficulty in vaporizing non-volatile and thermally labile molecules without degrading them.

Other detectors In addition to the highly popular detectors mentioned above, numerous other detectors have been used in HPLC including Fourier transform infrared (FTIR), radioactivity, element selective, and photoionization. Two detectors which have been gaining in popularity for specific applications are chiroptical for optically active compounds and evaporative light scattering for triglyceride analysis.

Data Collection and Output System

A data collection and output device (e.g. computer, integrator, or recorder) is connected to the electronic output of the detector. The data-collection device takes the electronic signal produced by the detector and outputs a plot of response versus time. This resulting chromatogram can then be evaluated for both qualitative and quantitative information. Recorders are rarely used today on their own. Both integrators and computers can integrate the peaks of a chromatogram and have the added advantage of being able to store chromatograms for post-collection processing. The data from computer-based collection systems can also be exported to other software programs and around the world by e-mail or over the Internet. In addition, the computer is typically able to communicate with and control the entire HPLC system. Hence, the majority of modern HPLC systems are fitted with computer control, data collection, and output systems.

Post-Detection Eluent Processing

After the eluent passes through the detector, it is often directed to a waste container. The waste container should be properly labelled for eventual disposal by environmentally acceptable means. If isocratic chromatography is being performed, a mobile-phase recycling device can be added after the detector. While the instrument is running and no injections are being made or during periods of the separation when no peaks are being eluted, the solvent-recycling device will direct clean mobile phase back to the mobile-phase reservoir.

If collection of the eluted peaks is needed, a fraction-collection device is added to the system after the detector. The collection of the peaks by the fraction collector can be done on the basis of a fixed interval of time or mobile-phase volume or via the output signal from the detector. Fraction collectors can also be under the control of an HPLC's computer for ease of use.

Connective Tubing and Fittings

The connective tubing in the HPLC system should be made of material inert to the solvents and constituents of the mobile phase. Often tubing is made of stainless steel or polymer-based materials (e.g. PEEK®, Teflon®, etc.). The connections between the tubings and HPLC components are made with fittings and unions designed to minimize excess volume, or dead volume. Zero dead volume (ZDV) and low dead-volume (LDV) fittings are necessary to reduce band-broadening effects. Also, great care should be used when assembling columns and fittings so that they match properly. Tubing should be cut flat and fit flush, and all fittings should be zero dead volume. Any

extra-column volume compromises separation efficiency. Polymer-based, or PEEK®, tubing and fittings throughout the chromatographic flow path are becoming very popular. PEEK tubing is available in a wide range of sizes, is colour-coded for ease of size selection, is easy to work with, is tolerant to a wide range of buffer and solvent conditions, and is impermeable to oxygen.

The effects of band-broadening are not important prior to injection; therefore, the inner diameter of the tubing from the pump to the injector/autosampler should be as large (i.e. typically 0.030 inch i.d.) as possible (i.e. to reduce system back-pressure) while maintaining high-pressure strength. From the injector to the column to the detector, all tubing should be as short as possible and of the narrowest diameter available to minimize extra-column effects. Post-injector tubing diameters are often 0.01–0.005 inch i.d.

Related HPLC Techniques

The HPLC system described above was based on the dimensions of a typical analytical system, otherwise known as ‘normal-bore chromatography’. The same basic components and designs are used in both micro- (i.e. column dimensions of 1–2 mm i.d.) and preparative systems, which have much larger column dimensions.

Microchromatographic techniques include micro-bore, nanobore, and capillary chromatography, which have column inner diameters of 2 to 1 mm, 1 to 0.3 mm, and less than 300 µm, respectively. Most importantly, microchromatographic systems require smaller extra-column volumes than normal-bore systems. Hence, great pains should be taken to use the smallest inner-diameter tubing available, zero dead-volume fittings, smaller injection volumes, and smaller detection cell volumes. Microchroma-

tographic systems are employed when sample volume is limited.

If compound purification or isolation is intended, preparative chromatography is used. Since a large quantity of material is to be injected in order to isolate a significant quantity of analyte, column capacity and, hence, column diameters are larger. Column diameters in preparative HPLC can be on the order of metres. The high flow rates needed for these large-scale systems require the use of special pumps and larger tubing throughout.

Ion pair chromatography is a widely used reversed phase liquid chromatographic technique for the

separation of ionic analytes. Retention of ions in ion pair chromatography is determined by many experimental parameters and it therefore provides an effective tool for obtaining chromatographic separation between ionic analytes. A major part of this article discusses the influence of the most important

parameters on retention. A short presentation of the areas of application of ion pair chromatography, as well as some practical guidelines for its use, is also included.

Introduction to Ion Pair Chromatography

Ion pair chromatography (IPC) is an effective reversed-phase liquid chromatographic (RPLC) technique for separation of organic ions and partly ionized organic analytes. The technique utilizes the same types of stationary phases and mobile phases as RPLC; the main characteristic for IPC is that an ion pair reagent is added to the mobile phase. The ion pair reagent is usually an alkylsulfonate, an alkylsulfate or an alkylammonium salt. The high efficiency of RPC columns compared with columns used in ion exchange or ion chromatography also makes IPC a valuable alternative to these techniques.

The purpose of adding an ion pair reagent to the mobile phase is usually to change the retention time of ionic analytes. By varying the mobile phase concentration of the ion pair reagent, the retention factor for an oppositely mono-charged analyte can be continuously increased by a factor of 10–20 compared to the value with no added ion pair reagent. Correspondingly, it is possible to continuously reduce the retention factor for a similarly mono-charged analyte by a factor of 10–20. The retention factor for non-charged analytes is usually more or less unaffected by the presence of the ion pair reagent.

Ion pair extraction, i.e. extraction of ionized solutes into organic phases by adding an oppositely charged ion to the system, has been used for many decades. In this technique, the distribution of an ion into the organic phase is enhanced by the formation of an ion pair between the two oppositely charged ions. The pioneering work in IPC by Schill and co-workers in Uppsala was performed in the liquid–liquid partition mode. The extraction of an ion pair to the organic phase was considered to be the cause of retention, and the name ion pair chromatography originates from this early application. When covalently bonded non-polar stationary phases were introduced, important contributions to the further development of IPC were, among others, made by the research groups of Horváth, Knox, Schill and Haney.

IPC has been applied in almost all areas of analytical chemistry where chromatography is used. Since many drugs are basic or acidic, the driving force for the development of IPC came from the pharmaceutical industry where today it is used on a routine basis.

Of particular current interest is chiral separations of pharmaceutical compounds by using a chiral ion pair reagent. In IPC, water-rich mobile phases can be employed with a variety of buffers and ionic and non-ionic additives and the technique is therefore suitable for separation of important classes of biomolecules and specifically amino acids, peptides, proteins and nucleic acids. In the food industry, IPC is used for the analysis of water-soluble vitamins, caffeine, theobromine, amines, etc.

For the separation of inorganic cations and anions IPC is often used as an alternative to ion (exchange) chromatography and in these applications it is usually referred to as ion interaction chromatography. In ion interaction chromatography, the ion pair reagent is usually called the ion interaction reagent. The technique has been used, for example, in the area of environmental analysis for the separation and analysis of nitrate and nitrite. Another technique that is closely related to ion pair chromatography is micellar chromatography. Here the concentration of ion pair reagent in the mobile phase is so high that micelles are formed, i.e. the concentration of the ion pair reagent in the mobile phase is above the critical micelle concentration (CMC). Micellar chromatography is treated in a separate article.

When the analyte ion lacks properties that make it easily detectable by commonly used detectors, IPC in the indirect detection mode can be used. The basis of this method is that a constant concentration of a detectable ion pair reagent is added to the mobile phase. In the chromatographic zone, where the non-detectable analyte ion is present, a change from the otherwise constant concentration of the detectable ion pair reagent is induced by the analyte. Depending on the relative properties of the analyte and the ion pair reagent, the concentration of ion pair reagent in the analyte zone may be either higher or lower than in the mobile phase.

Retention and selectivity in reversed-phase IPC are influenced by a large number of experimental parameters. These parameters are given in **Table 1** together with a short description of their effect on retention. Briefly, for the separation of a particular set of analyte ions the parameters that are most important are type and concentration of ion pair reagent, type and concentration of organic modifier, and mobile phase pH. By varying these parameters while keeping the others constant within sensible ranges, an acceptable separation is usually obtained. A rational use of IPC is facilitated by a basic knowledge of the impact of the different parameters on retention. A more detailed analysis of the role of the most important parameters is presented below.

Table 1 Effect on retention of increasing the value of different chromatographic variables in reversed-phase ion pair chromatographic systems

Variable	Effect on k for oppositely charged solute	Effect on k for similarly charged solute
Increasing charge of analyte ion ($z_B = \pm 1, 2, \dots$)	Increases the slope of the $\ln k_{CB}$ vs $\ln c_A$ relation	Increases the absolute value of the slope of the $\ln k_{CB}$ vs $\ln c_A$ relation
Increasing charge of pairing ion ($z_A = \pm 1, 2, \dots$)	Slightly decreases the slope of the $\ln k_{CB}$ vs $\ln c_A$ relation	Slightly decreases the absolute value of the slope of the $\ln k_{CB}$ vs $\ln c_A$ relation
Increasing concentration of pairing ion (c_A)	Increases	Decreases
Increasing hydrophobicity of pairing ion (K_A)	Increases	Decreases
Increasing concentration of organic modifier (φ)	Decreases. The slope of the $\ln k_{CB}$ vs φ relationship becomes steeper compared with the regular RP slope	Decreases. The slope of the $\ln k_{CB}$ vs φ relationship becomes less steep compared with the regular RP slope
Increasing polarity of the organic modifier	The slope of the $\ln k_{CB}$ vs φ relationship decreases	The absolute value of the slope of the $\ln k_{CB}$ vs φ relationship increases
Increasing ionic strength (I)	Decreases	Increases
Type of stationary phase	A parallel shift of the $\ln k_{CB}$ vs $\ln c_A$ relationship occurs for both positively and negatively charged analytes when using different columns	
Eluent pH	Retention of the ionized form increases; it can become even larger than the regular RP retention of the non-ionized form	Retention of the ionized form decreases

Retention Theories for Ion Pair Chromatography

Stoichiometric Theories

In this article IPC means liquid chromatography performed on columns with covalently bonded non-polar stationary phases, in combination with polar mobile phases containing an ion pair reagent. The earliest retention theories for IPC were stoichiometric, i.e. the retention is assumed to be caused by the formation of a 1 : 1 stoichiometric complex between the ion pair reagent and the oppositely charged analyte ion. Depending on the particular theory, complex formation is considered to take place in the mobile phase or in the bonded phase. Other theories consider the ion pair reagent to be adsorbed to the stationary phase surface and describe retention as a result of a stoichiometric ion exchange process between the analyte ion and the counter ions to the ion pair reagent. In 1981 it was pointed out by Knox and Hartwick that many of the proposed stoichiometric retention theories are thermodynamically equivalent and that it is therefore not possible to distinguish them from each other by retention measurements alone.

The physicochemical cause of retention in ion pair chromatography has been a controversial issue. Because of this disagreement many alternative names

have been proposed for this technique. These include: dynamic ion exchange chromatography, ion-interaction chromatography, hetaeric chromatography, and soap chromatography. Correspondingly, many names have been used for the ion pair reagent.

Non-stoichiometric Theories

Modern retention theories recognize that the layer of the bonded phase is so thin that the surface area to bonded phase volume ratio is extremely high. As a consequence, the surface science view on adsorption of both the analyte and the ion pair reagent to the stationary phase can be applied. In these theories, the electrostatic interaction between the ion pair reagent and the analyte ion leads to a non-stoichiometric retention theory. The non-stoichiometry is a consequence of the fact that the electrostatic interaction is long ranged and therefore gives rise to a multibody interaction (Figure 1).

The common basis of modern retention theories is that a charged surface is created when the ion pair reagent adsorbs at the interface between the polar mobile phase and the hydrophobic stationary phase. The inorganic counterions to the ion pair reagent are territorially bound to the charged surface in a diffuse layer and a diffuse double layer is formed. Physically this results in a difference in electrostatic potential, $\Delta\Psi_0$, between the bulk of the mobile phase and the surface ($\Delta\Psi_0$ has the same physical origin as the more

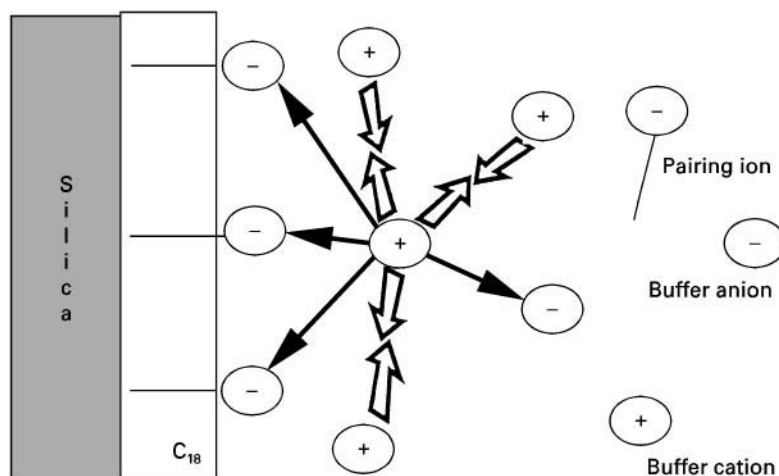

Figure 1 Schematic illustration of the long-range nature of electrostatic forces between ions in typical ion pair chromatographic systems. Open and full arrows represent electrostatic repulsion and attraction forces, respectively. (Reproduced with permission from Bartha Á and Ståhlberg J (1994) *Journal of Chromatography A* 668: 255.)

frequently encountered zeta-potential, although they may differ in their numerical value). For a positively charged ion pair reagent the numerical value for $\Delta\Psi_0$ is positive and for a negative reagent it is negative. Qualitatively, the charging of the stationary phase surface infers that the retention of analyte ions of opposite charge to the pairing ion increases due to electrostatic attraction. It also infers that the retention of analyte ions of similar charge to the

pairing ion decreases due to electrostatic repulsion (Figure 2).

Several non-stoichiometric theories have been proposed, which all use the difference in electrostatic potential between the mobile and stationary phase as a parameter that influences the retention of an ionic analyte. However, there are important differences between the theories in the physical description and also in the role that the electrostatic surface potential plays in retention. For example, in the theory proposed by Cantwell and co-workers, retention is considered to be due to a mixed ion exchange and electrostatic effect. The disagreement today among the proponents of non-stoichiometric theories seems to be on how retention is best described under conditions of high surface loadings of the ion pair reagent, i.e. when the electrostatic surface potential is higher than ± 60 mV. The disagreement is a consequence of the fact that under these conditions a number of different, not fully understood, physical phenomena may occur in the diffuse double layer.

Parameters Controlling the Retention factor in Ion Pair Chromatography

Theoretical Aspects

A simplified version of the surface adsorption double layer model for IPC provides a convenient framework for treating the influence of the various experimental parameters on the retention of medium-sized ($mw = 100\text{--}300$) mono- and di-charged organic ions. This is a non-stoichiometric theory developed for electrostatic surface potentials in the range 15–40 mV.

In this theory, the retention factor of an analyte ion in the absence of the ion pair reagent, k_{0B} , is related to its standard free energy of adsorption, ΔG_B^0 , according to:

$$k_{0B} = \phi \cdot \exp\left(-\frac{\Delta G_B^0}{RT}\right) \quad [1]$$

where the subscript zero denotes that the concentration of the ion pair concentration reagent is zero and ϕ is the column phase ratio. To a first approximation, the presence of the ion pair reagent on the surface does not change any property of the stationary phase other than its electrostatic potential. This infers that in the presence of the ion pair reagent the standard free energy of adsorption of the analyte changes to ΔG_t^0 where:

$$\Delta G_t^0 = \Delta G_B^0 + z_B F \Delta \Psi_0 \quad [2]$$

Here z_B is the charge of the analyte ion and F is the Faraday constant. ΔG_B^0 is usually referred to as the chemical part of the free energy of adsorption and $z_B F \Delta \Psi_0$ as the electrostatic part. Assuming that the retention of the analyte is due to adsorption to the stationary phase surface only, its retention factor, k_{cB} , in the presence of the ion pair reagent becomes:

$$\begin{aligned} k_{cB} &= \phi \cdot \exp\left(-\frac{\Delta G_B^0 + z_B F \Delta \Psi_0}{RT}\right) \\ &= k_{0B} \cdot \exp\left(-\frac{z_B F \Delta \Psi_0}{RT}\right) \end{aligned} \quad [3]$$

According to equation [3], the retention of an ionic analyte in IPC is determined by its retention in the absence of the ion pair reagent, the charge of the analyte ion and the electrostatic surface potential induced by the ion pair reagent. The influence of different experimental variables on the retention can for most cases be rationalized and quantitatively or semi-quantitatively described from eqn [3]. Deviations may occur, for example, when the value for k_{0B} is less than ≈ 0.5 , or when the surface concentration of the ion pair reagent is higher than 40–50% of the monolayer capacity of the surface.

The value for $\Delta \Psi_0$ is primarily a function of the surface concentration of the ion pair reagent and of the ionic strength of the mobile phase. The relationship between these variables can be obtained from solving the Poisson–Boltzmann equation for charged surfaces in contact with an electrolyte solution. When the electrostatic surface potential is below ± 25 mV the solution shows that there is a linear relation between the surface concentration of charges

and $\Delta \Psi_0$:

$$\Delta \Psi_0 = \frac{z_A n_A F}{\kappa \epsilon_0 \epsilon_r} \quad [4]$$

where n_A is the surface concentration of the ion pair reagent (mol m^{-2}), κ is the inverse Debye length ($1/\text{m}$), ϵ_0 is the permittivity of vacuum and ϵ_r is the dielectric constant of the mobile phase (dimensionless). The numerical value for κ is proportional to the square root of the ionic strength of the mobile phase.

In practice, it is not the surface concentration of the ion pair reagent but its mobile phase concentration that is experimentally controlled. The relationship between these two is determined by the adsorption isotherm of the ion pair reagent onto the stationary phase surface. In analogy with the discussion concerning the adsorption of the analyte ion, the free energy of adsorption of the ion pair reagent is divided into a chemical and an electrostatic part. Physically this means that the electrostatic surface potential created by the ion pair reagent must be included in its own adsorption isotherm. The simplest is the surface potential-modified linear adsorption isotherm:

$$n_A = n_0 K_A c_A \cdot \exp\left(-\frac{z_B F \Delta \Psi_0}{RT}\right) \quad [5]$$

where n_0 is the monolayer capacity of the surface, c_A is the mobile phase concentration of the ion pair reagent and K_A is its association constant to the stationary phase. The exponential term in the equation accounts for the electrostatic repulsion induced by the adsorbed ion pair reagent itself and it gives rise to a nonlinear adsorption isotherm. Equation [5] has been experimentally verified in many different reversed phase ion pair systems and can be used when n_A is less than $0.3n_0$.

After making some approximations it is possible to derive eqn [6] from eqns [3]–[5]

$$\begin{aligned} \ln k_{cB} &= \ln k_{0B} + \frac{-z_A z_B}{(z_A^2 + 1)} \left[\ln n_0 K_A + \ln c_A \right. \\ &\quad \left. - \frac{1}{2} \ln I + \text{const.} \right] \end{aligned} \quad [6]$$

where I is the mobile phase ionic strength. This equation in a convenient way separates the influence of the different experimental variables on retention. For oppositely mono-charged analyte and ion pair reagent, the equation is approximately valid in the interval 2–10 for the k_{cB}/k_{0B} ratio.

Measurements were made in methanol–aqueous phosphate buffer (pH 2.1, 10 : 90 v/v). (Reproduced with permission from Bartha Á and Ståhlberg J (1994) *Journal of Chromatography A* 668: 255.)

Charge of the Analyte and Ion Pair Reagent Ion

The influence of the charge of the analyte ion on retention when the mobile phase concentration of the ion pair reagent varies can be understood from eqn [6]. When $z_A = +1$ and $z_B = -1$, the equation predicts that in a $\ln k_{CB}$ vs $\ln c_A$ plot the slope of the straight line is equal to $1/2$ and when $z_B = z_A = -1$ it is equal to $-1/2$. Examples of experimental data for these two cases are shown in Figure 3.

For multiple charged ion pair reagents, the non-linearity of the adsorption isotherm becomes more pronounced than for monocharged reagents. Quantitatively, this is described in eqns [4]–[6] through the value for z_A ; when $z_A = +2$ eqn [6] predicts that the slope of the $\ln k_{CB}$ vs $\ln c_A$ plot is $2/5$ for a negatively mono-charged analyte ion and $4/5$ for a di-charged ion. An example is shown in Figure 4 where the di-charged hexamethonium bromide ion is used as ion pair reagent. The solid lines in the figure corresponds to the theoretically predicted slope.

Type of Analyte Ion and Ion Pair Reagent

In a reversed phase chromatographic system, the ionized form of a molecule has a much lower retention factor than the corresponding non-ionized form. The main reason is that charged species have a lower energy in a medium of high dielectric constant (i.e. the mobile phase) than in a medium of low dielectric constant (i.e. the hydrophobic surface layer). Within a series of analyte ions of identical charge but differ-

ent hydrophobicity, the retention order follows the same rules as for non-ionized analytes, i.e. the more hydrophobic analyte is more retained. This property is reflected in eqns [3] and [6] by different k_{OB} values for different fully ionized analytes.

Figure 4 Retention factor data for mono-charged (\triangle , 1-naphthylamine-4-sulfonic acid; $*$, 6-naphthol-2-sulfonic acid) and double-charged sulfonic acids (\square , 2-naphthol-6,8-disulfonic acid; \diamond , naphthalene-2,7-disulfonic acid) as a function of eluent concentration (c_A) of the double-charged pairing ion, hexamethonium bromide ($z_A = +2$). (Reproduced with permission from Bartha Á and Ståhlberg J (1994) *Journal of Chromatography A* 668: 255.)

Figure 5 Retention factor of adrenaline as a function of the stationary phase surface concentration (n_A) of sodium butyl- (Δ), hexyl- ($*$) and octyl- (\square) sulfonate pairing ions measured at constant ionic strength (175 mM Na^+) of the phosphate buffer (pH 2.1) on an ODS-Hypersil column. (Reproduced with permission from Bartha Á and Ståhlberg J (1994) *Journal of Chromatography A* 668: 255.)

Under the condition of identical mobile phase concentration of two ion pair reagent ions of different hydrophobicity, the more hydrophobic reagent ion gives a higher retention for an oppositely charged analyte. This is attributed to higher adsorption to the stationary phase surface of the more hydrophobic reagent and a correspondingly higher induced electrostatic surface potential. Since a relative change in retention factor is primarily caused by a change in electrostatic surface potential, it is the surface concentration of the ion pair reagent, and not its detailed molecular structure, which is of importance for retention changes. This important fact is illustrated in **Figure 5** where the retention factor of adrenaline is solely a function of the surface concentration of the three different alkylsulfonates and is independent of the type of ion pair reagent.

Concentration of Organic Modifier in the Mobile Phase

In reversed-phase liquid chromatography, the effect of organic modifier concentration on the retention factor for non-charged analytes is usually described according to eqn [7]

$$\ln k_B(\phi) = \ln k_{wB} - S_B \phi \quad [7]$$

where k_{wB} is the retention factor for analyte B in a water-buffer mobile phase, S_B is a constant for a given analyte-solvent combination, and ϕ is the organic modifier concentration in the mobile phase. The thermodynamic interpretation of eqn [7] is that the free energy of adsorption of the analyte B to the

reversed phase surface is linearly dependent on the organic modifier concentration. In an ion pair system the retention depends on the adsorption of two components, the ion pair reagent and the analyte, respectively. There are therefore two different adsorption energies, and correspondingly, two equilibrium constants for adsorption involved. The logarithm of both these equilibrium constants approximately obey equation [7]. That is, besides the effect on the analyte ion a linear relation with coefficient, S_A , describes the change in $\ln K_A$ with changing organic modifier concentration. The final result is that $\ln k$ for an analyte ion depends on both the value of S_B and S_A . For a mono-charged analyte and ion pair reagent of opposite charge, eqn [6] gives that the slope of the $\ln k_{cB}$ vs ϕ relation becomes $S_B + \frac{1}{2}S_A$, while if they are of similar charge the slope becomes $S_B - \frac{1}{2}S_A$.

In **Figure 6** the logarithm of the retention factor for a positively charged (phenylalanine) and a negatively charged (naphthalene-2-sulfonic acid) analyte is plotted as a function of the volume concentration of methanol in the absence and presence of sodium octylsulfonate, respectively. The dashed line in both figures corresponds to the slope S_B for the corresponding analyte ion, whereas in **Figure 6A** the solid line corresponds to the slope $S_B + \frac{1}{2}S_A$ and in **Figure 6B** it corresponds to the slope $S_B - \frac{1}{2}S_A$.

Effect of pH of the Mobile Phase

For weak acid and basic analytes the mobile phase pH value influences the degree of ionization and con-

Figure 6 Retention factor for (A) phenylalanine and (B) naphthalene-2-sulfonic acid as a function of the methanol concentration (ϕ) in the phosphate buffer (pH 2.1 and constant ionic strength 175 mM Na^+) in the mobile phase in the absence (□) and presence (△) of 5 mM sodium octylsulfonate pairing ion. (Reproduced with permission from Bartha Á and Ståhlberg J (1994) *Journal of Chromatography A* 668: 255.)

sequently its retention. In a reversed-phase system, with no ion pair reagent added, the retention factor k_B is the weighted sum of the retention factor for the charged, k_{iB} , and the uncharged, k_{uB} , species, respectively:

$$k_B = (1 - f) \cdot k_{uB} + f \cdot k_{iB} \quad [8]$$

where f is the fraction of charged analyte in the mobile phase at the given pH value. Addition of an ion pair reagent to the mobile phase mainly influences the retention of the ionized fraction of the analyte. Furthermore, the influence can be treated with the same formalism as for a fully ionized analyte, i.e. eqn [8] takes the following form:

$$k_B = (1 - f) \cdot k_{uB} + f \cdot k_{oiB} \cdot \exp\left(-\frac{z_{iB} F \Psi_0}{RT}\right) \quad [9]$$

where k_{oiB} is the retention factor of the fully ionized form of the analyte in the absence of the ion pair reagent. Figure 7 shows the retention of a weak base, adenine ($\text{p}K_a = 4.12$), as function of pH in the absence and in the presence of an oppositely charged ion pair reagent (5 mM sodium octylsulfonate).

Choice of Experimental Parameters in IPC

Large changes in retention of ionic analytes may occur when the pH, the concentration of organic

modifier and the concentration of ion pair reagent is varied. The purpose of IPC is to take advantage of these variations in order to achieve a separation.

Figure 7 Retention factor for the weak base adenine ($z_{iB} = +1$) as a function of pH in the mobile phase in the absence (■) and presence (●) of the pairing ion sodium octylsulfonate. The theoretical retention plots in the absence of the pairing ion (dashed line, $\Psi_0 = 0$) and in its presence (solid line) are calculated from eqn [9] with the following parameters; $\text{p}K_a = 4.12$, $k_{uB} = 8.2$, $k_{iB} = 2.07$, $z_{iB} F \Psi_0 / RT = -2.398$. (Reproduced with permission from Bartha Á, Ståhlberg J and Szokoli F (1991) *Journal of Chromatography* 552: 13.)

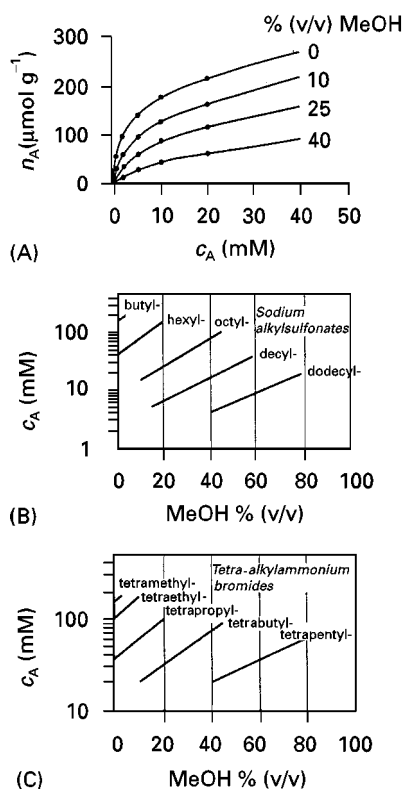

Figure 8 (A) Adsorption isotherm of octylsulfonate to a C_{18} -RP-column with the concentration of MeOH in the mobile phase as parameter. (B) Recommended alkylsulfonate type and concentration for different MeOH concentrations in the mobile phase, and (C) recommended tetraalkylammonium ion type and concentration for different MeOH concentrations in the mobile phase. (Reproduced with permission from Bartha Á, Vigh Gy and Varga-Puchony Z (1990) *Journal of Chromatography* 499: 423.)

This means that method development in this area usually is successful but requires a basic understanding of the physical processes that determine the retention.

In the development of an IPC method, the first point to consider is the relationship between the pK_a value of the analyte ions and the pH value of the mobile phase. To obtain a robust system the mobile phase pH should deviate from the pK_a value with more than two units. The pH is controlled by using a 10–50 mM salt buffer in the mobile phase. The buffer salt not only adjusts the pH but also controls the strength of electrostatic interaction between the ionic analytes and the ion pair reagent.

For changing the retention of an ionic analyte there are mainly three parameters to be varied: the type and mobile phase concentration of the ion pair reagent and the concentration of the organic modifier. The physically important parameter that is changed when these three parameters vary is the surface concentra-

tion of the ion pair reagent, and the corresponding electrostatic surface potential. A guideline for choosing type and concentration of positively and negatively charged ion pair reagents, respectively, as a function of the concentration of MeOH in the mobile phase is shown in Figure 8. The general rules for converting from MeOH to other common types of organic modifiers also apply in this case, e.g. 20% MeOH in the mobile phase corresponds to approximately 8% acetonitrile.

Introduction

The 1990s have seen the birth of high performance preparative liquid chromatography (HPPLC) and its recognition by the pharmaceutical and fine chemical industries as a very powerful and versatile purification technique. In contrast to traditional low performance/low pressure preparative chromatography, HPPLC is based on the use of columns of medium to high efficiency, operated at high mobile phase velocities, and consequently at moderate to high pressure – conditions quite similar to those met in analytical chromatography.

The very early work carried out in liquid chromatography at the beginning of the twentieth century (at a time when liquid chromatography was used for preparative purposes only) made use of particles 1–15 μm in diameter. For several reasons, preparative liquid chromatography (PLC) was later carried out with large particles ($>100 \mu\text{m}$) packed in columns of very low efficiencies operated at pressures close to atmospheric. Under such conditions, the kinetic properties of the columns are obviously very poor; the preparative separations require large quantities of mobile phase, long separation times and are expensive. For this reason, for a long time PLC was considered to be inappropriate for industrial purifications and was the choice of last resort. There were three reasons for this poor image: first, the misunderstanding of the effect of the column efficiency and the lack of a theoretical framework to describe the behaviour of columns under highly overloaded conditions; second, the use of low-quality packing materials (large particle size and large size distribution); and third, the lack of proper equipment in general, and adequate column technology in particular. Now that these problems have been addressed, PLC has many advantages.

Particular Effects Related to Column Overloading

For the sake of simplicity, the following discussion is limited to a binary mixture, but the phenomena described are the same for more complex mixtures. It is also assumed that the adsorption isotherms are Langmuirian. This is the case for most practical situations

in chromatography. The total band broadening occurring in the column is the combination of two contributions: that of the intrinsic column efficiency (kinetic term – the column efficiency under an infinitely small injected quantity) and that of the finite mass of product injected (thermodynamic term – related to the amount injected). The equipment itself, besides the column, can also contribute to band broadening, but this is not considered in the present discussion.

When a sufficiently large quantity of product is injected, the thermodynamic term (which is proportional to the injected quantity, to a first approximation) becomes larger than the kinetic term and the total band broadening is primarily controlled by the quantity injected. It has been concluded from this observation that, under high mass overload, there is no reason to use efficient columns in PLC since the contribution of the intrinsic column efficiency is masked by the thermodynamic contribution. This is true as long as pure products are injected, which is obviously not the case when PLC is used.

When a mixture of two products is injected, the elution bands occupy the same section of the column during a certain fraction of their migration through the bed. When this happens, the molecules of each component compete for the same retention sites. When the injected quantity becomes sufficiently large, the molecules that have more affinity for the stationary phase prevent the other ones from interacting with the adsorbent. As a result, the weakly retained product is eluted faster than expected. This is known as a displacement effect. This effect is particularly strong when the weakly retained product is present at a smaller concentration than the strongly retained one. Under such conditions, the peak for the weakly retained component is not only eluted more quickly than if it were injected alone, but it is also narrower and has the typical shape shown in Figure 1A. Better separation is achieved than would be found if the displacement effect were not effective. When the more strongly retained compound is at lower concentration than the weakly retained one, the peak for the second compound is broader than it would be if injected alone. It also starts to be eluted earlier, an effect known as the tag-along effect (see Figure 1B).

It is clearly preferable to optimize the choice of the chromatographic conditions so that the first product is the one at the smaller concentration (typically, the impurity to be removed). Under these conditions, the region where the two products interfere is strongly

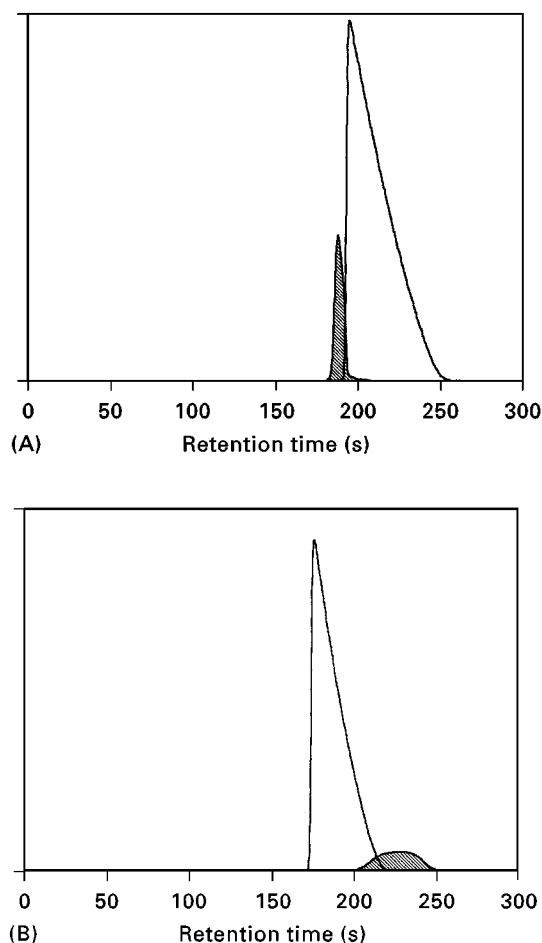

Figure 1

controlled by the column efficiency (see Figure 2) and increasing the column efficiency results in the possibility of injecting (much) more product or recovering more product for a given injected quantity. The possibility of using displacement effects and injecting large quantities is thus associated with columns of sufficient efficiency. Such columns enable higher

production rates, reduce solvent consumption and purification times, and thus decrease purification costs.

The displacement and tag-along effects, as well as the role of the various operating parameters, have been modelled by several groups. Unfortunately, it is not yet possible (and it is questionable if it will be in a near future) to make accurate predictions of the properties of a given chromatographic system under moderate and severe overloading conditions, and thus optimize the operating conditions to minimize the purification cost, for instance. The rigorous treatment of Guiochon and co-workers, based on the simultaneous resolution of the mass balance equations for the various species involved in the chromatographic process, involves numerical integration of a set of differential equations. This treatment is based on the model of competitive Langmuir isotherms and the approach is not simple since it requires knowledge of the composite adsorption isotherms. Major difficulties lie in experiments to measure these composite isotherms and the lack of suitable models to describe them with sufficient accuracy.

Column Technology

In order to get efficient columns of large diameter (i.e. > 5 cm) for preparative purposes, it is necessary to have a packing material of adequate quality and also the appropriate column technology. Column technology is a very critical issue, since it is known that above a certain diameter columns tend to be unstable because of bed settling and the resulting formation of voids in the packing. These voids are very detrimental to the column efficiency and are responsible for band distortion. In addition, large columns are potentially more difficult to pack than small ones, particularly when small particles ($< 50 \mu\text{m}$) are used. Indeed, the high pressure slurry-packing technique used to pack

Figure 2

Figure 3 Methods of dynamic compression. (A) Radial compression; (B) axial compression.

analytical columns cannot be used for large diameter columns for both practical and technical reasons.

Various solutions have been proposed to solve the problem of bed stability. It seems that the best approach is to compress the bed of particles, either radially (using columns with flexible walls immersed in a pressurized fluid) or, preferably, axially using a piston (see **Figure 3**). This bed compression must be dynamic so that voids are eliminated as soon as they form. Using dynamic axial compression, it is possible to pack columns of large diameter with small particles offering the same efficiency as analytical columns (see **Figure 4**). This technology is particularly versatile because it gives the operator the possibility of packing the column very easily and quickly with

any type of material. This is clearly important for equipment used in production where downtime has to be minimized. In addition, the length of the bed can be easily adjusted to optimize the column efficiency. Finally, whatever the compression technique used, it is very important to design the column ends properly. Indeed, in order to generate piston flow and avoid band distortion due to unequal flow distribution, it is necessary to spread the flow of liquid evenly across the cross-section of the column.

Packing Materials

The best column technology is useless without the proper packing material. There are two main aspects to consider when selecting the packing material: chemical and physical. The chemical aspect is related to the chemistry of the purification problem and is not discussed here since it is very much product dependent. A material well suited for a given application may be inadequate for another. The physical aspects, however, can be discussed in general terms. The various models of HPPLC have shown that there is an optimum value of the ratio d_p^2/L for any separation problem (d_p is the particle size and L the column length). In typical conditions, for columns operated at a pressure of 30 to 60 bar, an 'optimum' particle size is about 10–20 μm with a column length between 20 and 50 cm. Accordingly, rather small particles have to be used for PLC.

It is also very important to keep the particle size distribution as narrow as possible, since small particles in the distribution have a very strong effect on the column permeability and large particles strongly influence the column efficiency. In other words, a material with a large size distribution tends to produce low-efficiency columns with low permeability. It is usually considered that the ratio d_{p10}/d_{p90} should be less than 1.5 for a good material (d_{p10} and d_{p90} being the particle sizes corresponding to 10% and 90% of the cumulated volume-based size distribution).

Besides the average particle size and the size distribution, other physical properties of the packing material are important, particularly the specific surface area and the pore size. It is desirable to maximize the surface area of the material in order to increase its adsorption capacity. Increasing the surface area, however, usually means decreasing the pore size and thus the access of the molecules to the internal pores of the particles. There exists an optimum pore size and specific surface for each compound to be purified.

Among the other important physical parameters, one should also mention the mechanical strength of the particles, since they must resist the stress of the compression technique used.

Figure 4 Comparison of chromatograms from columns. (A) 25 cm \times 4.6 mm and (B) 25 cm \times 150 mm.

Optimization of Separation Conditions

The optimization of PLC is not a simple task since many parameters have to be taken into account: kinetics (column efficiency and column design in terms of d_p and L), thermodynamics (choice of the chromatographic system, temperature, degree of column overloading, etc.) and economics. The necessity to take into account economic aspects is important since the most favourable conditions in terms of purification cost do not necessarily correspond to the best chromatographic conditions in terms of quality of separation. Indeed, a better chromatographic mobile phase providing more selectivity may turn out to be more expensive to buy or to recycle (mobile phase recycling is often essential to keep purification costs low). This means that such parameters as the heat of vaporization of the mobile phase and its cost have to be considered. The mobile phase viscosity is also very important since it controls not only the velocity of the eluent at a given operating pressure (and thus the time required for the separation), but also the values of the diffusion coefficients of the products in the mobile phase, and accordingly the column efficiency. Very viscous eluents (such as propanol–water mixtures, for example) should be avoided in preparative chromatography.

A general economic analysis of a purification process by PLC indicates that there are typically two situations to be considered. When the quantity to be purified is low, the optimization should be aimed at maximizing the production rate because time (labour) is the largest contribution to the purification cost. When large quantities have to be processed, the optimization should be aimed at reducing the solvent cost (solvent consumption and regeneration). Many strategies can be envisaged to reduce the cost of PLC, depending on the conditions of the purification in terms of expected production, required purity and recovery ratio, etc. For instance, a purification can be made in several steps. This is often advisable when the concentration of the product of interest in the crude feedstock is low (i.e. less than 50%). In this respect, it is important to clean up the mixture to be purified as much as possible before injecting it (using a preliminary treatment such as flash chromatography, for example).

Various techniques can be used to reduce time and solvent consumption, and thus purification cost. Among them are shave-recycling and flip-flop. Shave-recycling consists of injecting (very) large quantities of feedstock – too large to provide satisfactory recovery of the product of interest at the expected purity. The fraction of the product peak where the purity is acceptable is collected and returned to the column

inlet (typically by using the solvent pump – adequate valving is required). During the second passage through the column, the separation between the product of interest and the impurities is further improved. The pure fraction of the product peak is then collected and, if necessary, the contaminated fraction of the peak is returned to the column for a third cycle. Typically, three or four cycles are made before a new large injection is performed. This shave-recycling approach saves on solvent (no fresh solvent is consumed when the column effluent is returned to the column inlet), reduces product dilution and decreases purification costs.

The flip-flop technique is an optimized back flush operation. It is very common for several impurities to be eluted after the product of interest. If these impurities are not removed from the column before the next injection is made, they can contaminate the product of interest in subsequent purification runs. Backflushing the column is often done to remove the strongly retained impurities. Flip-flop consists of performing the next injection a certain time after the backflush process has been initiated. During this time the weakly retained impurities of the next injection are eluted. Accordingly, during each elution run the flow direction in the column is reversed (hence the name flip-flop). This technique requires very good column stability because of these changes of flow direction.

Another powerful approach employed to reduce purification costs and solvent consumption is the recently ‘rediscovered’ technique of simulated moving bed (SMB), which is of particular interest for binary separation.

Simulated Moving Bed

When working on a large production scale, there are many arguments in favour of continuous processes. The majority of chromatographic processes are, however, batch processes that are incompatible with continuous production. Some years ago, continuous chromatographic processes were developed for large-scale separations in the food and petroleum industries. These processes solved some of the problems of implementation of large-scale chromatography. They are based upon the technique that is now known as simulated moving bed chromatography. The original application areas for this process were in the purification of *p*-xylene (a precursor of polyester plastics) and the separation of glucose from fructose to make high-fructose corn syrups, which are used in the soft drinks industry as a sucrose replacement. A few other applications also based upon this technology exist. There are perhaps 150 of these large-scale, low

pressure SMB systems in the world, responsible for the production of many thousands of tonnes of product each year. More recently, the combination of the new regulatory atmosphere in the pharmaceuticals industry, where pure enantiomers, of racemic drugs are becoming more and more in demand, together with the development of new media for the chromatographic resolution of enantiomers, has resulted in new areas of opportunity for SMB applications. These applications, by virtue of the high value of the products and the requirements for high purity in the industry, are for the most part operated using small particles in high pressure SMB equipment; this parallels the extensive use of HPLC purification methods in production for the pharmaceutical industry.

The basic principle of a true moving bed (TMB) unit is shown in Figure 5. The basis of TMB lies in the idea that in a chromatographic system the 'stationary' phase may be moved as well as the mobile phase. In a binary separation, the two components move at different velocities through the column. If one were to move the packing material in a direction opposite to that of the mobile phase in the column, one could choose a velocity of the packing material relative to that of the mobile phase such that one of the components moved in the original direction, carried by the mobile phase, while the other component, which spends a greater proportion of its time in the stationary phase, would be transported by the packing material in the opposite direction. By injecting in the middle of such a column, one product would emerge from each end of the column (the more retained product is often called the extract and the less retained product the raffinate, see Figure 5). Thus one could inject and collect product in a continuous fashion.

Figure 5 TMB unit.

In practice, many attempts have been made to realize such a countercurrent flow of packing material and mobile phase. None has been really successful, due mainly to the incompatibility of the needs of chromatography (tightly packed beds) and those of the transport of the solid particles (loose, fluid beds). The solution to the problem is to move the entire column, but in this case a column cut into short sections. In this way, rather than moving the bed in a continuous fashion, the individual sections of the column are moved periodically, such that the average bed speed remains that required for continuous separation. The feed inlet and the product outlets are arranged at the interfaces between the sections of the column, facilitating the entry and removal of materials. This principle operation simulates a true moving bed system and is thus called a simulated moving bed, SMB. It has been shown that when the number of columns exceeds about eight (this number depends on the separation problem considered), the performance of SMB is very close to that of TMB.

The removal of the products requires some special arrangements of flow rates in the system. The slower moving product (extract) moves during the separation phase in the direction of the packing material. If, in the section between the solvent inlet and the product outlet, the solvent flow is increased, a velocity will eventually be attained at which the product slows and becomes stationary. At a higher velocity, the product will reverse direction in the system and move with the solvent. This extra flow is removed from the product port; downstream of this port the velocities in the system remain the same as before. This means that in the first part of the column the product is moving toward the exit port in the same direction as the solvent. In the second section, the product is still moving with the packing material, also in the direction of the exit port. The only possible route for this product to take is out of the port, along with the extra solvent used to increase the flow rate beyond that critical for the change in direction of the product. In certain cases, this extra flow is not very large, and can be close in value to that of the feed.

At the other end of the system, the raffinate is removed by bleeding off some of the flow rate at the exit port. This reduces the solvent velocity in the final section of the column set such that the product moves with the packing material rather than the solvent. This means that, in this final section, the product is moved toward the exit port. In the penultimate section, the flow continues as before and the product again is moved in the direction of the outlet port. Thus, this product, too, is eluted from the system at the appropriate product port.

This arrangement for the removal of the products allows the solvent to be recycled. The solvent that elutes from the end of the column set does not (if the flow rates, etc., are controlled correctly) contain any product. It can then be redirected back to the solvent pump with the addition of a make-up flow to compensate for the excess flow removed in the raffinate and extract streams in comparison with that added by the feed. By the same token, the columns that pass the solvent inlet contain no product and so these can be added back at the other end of the column set for reuse. In this way a limited number of columns – usually between 8 and 16 – are used for the separations and the solvent use is also reduced in comparison with the batch operation. It should be noted that, in the majority of SMB system, the columns themselves remain stationary. Their movement is simulated by the use of switching valves, which are used to move the entry and exit ports around the column set.

In comparison with batch chromatography, SMB separations can be performed using smaller columns and less solvent than the equivalent batch separation. This is the result of the reduction in solvent required, the increased efficiency of use of the column and also the reduced need for column efficiency in terms of the number of theoretical plates in the system. Thus, although one requires a greater number of columns, the column set does not have to be as long as for a batch separation using the same column packing. This can lead to some bizarre solutions, in that batch HPLC separations are usually optimized for column lengths of 25 to 50 cm, using particle sizes of around 10 to 25 μm . The equivalent SMB separation, using the same particle size, would require column lengths of only 1 or 2 cm. This is not difficult to realize for a small-scale system, but becomes difficult if large diameter columns – of 50 to 100 cm internal diameter, for example – are envisaged. In this case, larger particle sizes are required in order that the columns can have reasonable product distribution to eliminate band deformation. The optimum size of the particles, columns, etc., for the separation then becomes a question of economics rather than of science.

Conclusions

HPPLC is certainly one of the most powerful purification techniques available today, and as such must be

considered by process and production engineers with the same attention as distillation, crystallization and other more traditional techniques. Provided it is properly used, HPPLC can be cheaper than traditional techniques, provide higher yields, higher degrees of purity and save on purification times, a particularly critical aspect in the highly competitive world of the modern pharmaceutical industry. Properly using HPPLC means understanding the behaviour of columns under highly overloaded conditions and using such beneficial effects as displacement effects. It also means using the right packing material, the right column efficiency and the appropriate column technology, as well as considering alternative strategies such as shave-recycling, backflush, SMB, etc. SMB is of particular interest for binary separations (but not only) and in the near future is expected to become the technique of choice for such separations at large and very large scales.

The separation of racemic compounds into their constituent enantiomers is now routinely performed by high performance liquid chromatography (HPLC) on chiral stationary phases (HPLC-CSPs). HPLC-CSPs are based on molecules of known stereochemical composition immobilized on liquid chromatographic supports. Single enantiomorphs, diastereomers, diastereomeric mixtures and chiral polymers (such as proteins) have been used as the chiral selector.

The first chromatographic separation of an enantiomeric compound on a CSP was reported in 1939 by Henderson and Rule. In this study, racemic camphor was enantioselectively separated on a column containing lactose as the adsorbent. Some of the other significant advances in this field are presented in Table 1.

The first commercial HPLC-CSP was developed by Pirkle and introduced by the Regis Chemical Company in 1981. By 1996, the number of commercially available HPLC-CSPs had grown to 110. The rapid increase in the availability of this technology was primarily due to its importance in the discovery, development and regulation of pharmaceutical products.

The Basis of Chiral Recognition

In order to utilize the wide range of available HPLC-CSPs effectively, it is important to identify the chiral recognition mechanisms operating on these phases. The enantioselective resolutions obtained on CSPs are the result of the formation of temporary diastereomeric complexes between the enantiomeric solute molecules and immobilized chiral selector (solute/CSP). The difference in energy between the resulting diastereomeric *R*-solute/CSP and *S*-solute/CSP complexes determines the magnitude of the observed stereoselectivity, whereas the sum total of the interactions between the solute and CSP, chiral and achiral, determines the observed retention and efficiency.

In order for two enantiomers to be separated chromatographically, there must be a difference in the free energies of binding (ΔG) between the two transient diastereomeric complexes. The energy difference arising from one such interaction would normally be insufficient to permit resolution. However, chromatography is a weighted time-averaged

view of many dynamic adsorption-desorption processes. These processes occur throughout the entire length of a column and their sum total can be sufficient to allow an observable difference in the retention times of two enantiomers.

The difference in free energy, $\Delta\Delta G$, needed for adequate chromatographic separation is influenced by the efficiency of the system employed. If the chromatographic system is of high efficiency, so that narrow peaks are observed, relatively small $\Delta\Delta G$ values will afford acceptable analytical-scale enantiomer separations.

For a chiral separation where t_{r1} is the retention time of the first eluting enantiomer, t_{r2} is the retention time of the second eluting enantiomer and t_0 is the retention time of an unretained solute (Figure 1). The partitioning of two enantiomerically related analytes between the stationary phase and the mobile phase is defined by the retention factors k_1 and k_2 .

$$k_1 = \frac{(t_{r1} - t_0)}{t_0} \quad [1]$$

Chiral Recognition Mechanisms

Chiral recognition is a specific aspect of the much broader area of molecular recognition. In chromatographic terms it usually implies the preferential interaction of one solute enantiomer with another enantiomer immobilized on an inert support. The

three-dimensional spatial arrangement of the solute requires a complementary three-dimensional structure with which to form a sufficient and necessary number of bonded and nonbonded interactions.

To specify the origin of enantioselective adsorption, one must specify the nature of the various interactions between the species involved. It is also necessary to define a model with which to characterize the requirements of enantioselective recognition. The first model was proposed by Easson and Stedman in 1933. In their mechanism, enantioselective receptor binding was the result of the differential binding of two enantiomers to a common site produced by a three-point contact model between ligand and receptor (Figure 2).

In this model, enantiomer 1 was more active than its enantiomorph 2 because 1 was more tightly bound to the receptor (3). The differential binding is a result of the sequence of the substituents, BCD , around the chirally substituted carbon atom which forms a triangular face of the tetrahedral bond array. For enantiomer 1, the sequence matches the complementary triad of binding sites on the receptor 3, $(B'C'D')$, leading to a three-point interaction. The enantiomorph 2 has a mirror image sequence, DCB , and its interaction with 3 occurs at only two of the three sites on the receptor surface, producing a relatively weaker ligand-receptor interaction.

The three-point interaction model was ignored for 15 years until Ogston resurrected it in order to explain the enzymatic decarboxylation of L-serine to L-glycine. The pivotal step in this conversion was the

Figure 2 Easson and Stedman's three-point interaction model of chiral discrimination.

stereoselective decarboxylation of the prochiral intermediate metabolite aminomalonic acid. In Ogston's model, the carboxylic moieties on the aminomalonic acid become nonequivalent due to the existence of three nonequivalent binding sites on the enzyme, one of which is responsible for the decarboxylation. Ogston's mechanism was a slight variation of the Easson and Stedman three-point model in that it did not require all three interactions to be attractive.

The first application of the three-point chiral recognition model in chromatography was published by Dalglish in 1952. In this work, amino acid enantiomers were resolved by paper chromatography and a three-point mechanism postulated for the interaction between the chiral cellulose stationary phase and the solute enantiomers. Since its introduction into enantioselective chromatography, the three-point interaction model has been the basis for the rational design of a large number of CSPs as well as the basic explanation for the enantioselective separations achieved on them.

Pirkle was the first to exploit this model in the design of synthetic, small molecule CSPs based upon derivatized amino acids. His initial HPLC-CSP was a 3,5-dinitrobenzoyl derivative of phenylglycine (Figure 3).

As in the Easson and Stedman model, interactions between the enantiomeric solutes and the CSP take place in the plane defined by $B'C'D'$. However, unlike the enzyme model, all of the attractive interactions are contained along the C' axis, including sites for hydrogen bond donation and acceptance, an amide

Figure 3 The three-point chiral recognition mechanism, as illustrated by a Pirkle-type CSP.

dipole which can participate in dipole–dipole interactions and the 3,5-dinitrobenzoyl moiety which can act as a site for π acid– π base interactions. The phenyl moiety and hydrogen atom on the B' and C' axes are sites of steric interaction.

In the chiral recognition process involving two enantiomers (BCD , DCB) attractive interactions between the amide moieties on the respective C (solute) and C' (CSP) axes create the solute–CSP complexes. The energetic difference between the R -solute–CSP and S -solute–CSP complexes arises from the steric fit of the BD and DB sequences on the enantiomeric solutes into the $B'D'$ sites on the CSP.

It is clear that the three-point interaction model works in a number of situations, especially with small synthetic CSPs. However, when large chiral biopolymers are used as the CSP, this model does not give an accurate description of how the dissymmetry of one molecule is perceived by a second or of how stereochemically equivalent moieties are distinguished from each other. The problem lies in the perception between point asymmetry and molecular asymmetry. In the former approach, a molecule is broken down into its parts, while in the latter it is viewed as the sum of its parts.

In principle, the three-point model is a static picture of a bimolecular process, essentially the lock-and-key model of enzymatic activity. In enzymology, the lock-and-key model has been superseded by the understanding that the pivotal step in enzymatic conversions involves mutually induced conformational adjustments of the substrate and enzyme – an induced molecular fit. When enantiomeric substrates are involved, the differences in enzymatic activity can be related to the energetic differences involved in the formation of the optimum substrate–enzyme complexes and the related transition state energies.

In analogy with the induced conformational fit utilized in enzyme kinetics, a conformationally driven chiral recognition mechanism has been described for the separation of α -alkyl arylacetic acids on an amylose *tris*(3,5-dimethylphenylcarbamate) CSP (AD-CSP). The chromatographic retentions and enantioselective resolutions of 28 chiral α -alkyl arylacetic acids were related to their respective structures through the construction of quantitative structure–enantioselective retention relationships (QSERR). The QSERR data were combined with molecular modelling studies and the results indicate that the enantioselective discrimination on the AD-CSP proceeds via a three-step process. These steps are:

- Step 1: Distribution of the solute to the stationary phase through hydrogen-bonding interactions between the acid moiety on the solute and amine moieties on the CSP.
- Step 2: Conformational adjustments of the solutes and insertion of the aromatic portion of the solute into a ravine on the CSP.
- Step 3: Stabilization of the solute–CSP complex through electrostatic and hydrogen-bonding interactions within the ravine.

This process can be illustrated using the enantioselective separation of *R*- and *S*-benoxaprofen on the AD-CSP. The optimal interaction between *S*-benoxaprofen and the CSP is illustrated in Figure 4.

Both *R*- and *S*-benoxaprofen form identical hydrogen-bonding interactions – and presumably the same

hydrophobic interactions as well – with the AD-CSP. The energetic differences between the diastereomeric *R*-benoxaprofen–CSP and *S*-benoxaprofen–CSP complexes arise from the internal energies of the two enantiomer conformations which are required to achieve the optimum interactions. The bonding conformation of *R*-benoxaprofen has been calculated to be approximately 250 cal mol^{-1} higher in energy than that of *S*-benoxaprofen. The theoretical enantioselectivity arising from this energy difference was estimated using eqn [9] $\{\Delta\Delta G = -RT \ln \alpha\}$, and the calculated α (1.52) was consistent with the observed α (1.82).

The determining factor in these processes is the molecular chirality of the biopolymer. Enzymes and amylose are large chiral biopolymers with distinct three-dimensional structures. While it is possible to assign specific electrostatic or hydrogen-bonding sites within these molecules, most interactions take place within cavities or ravines. Thus, a more accurate description of the chiral recognition process would be to replace the three-point interaction model with one based on molecular chiralities.

A general chiral recognition process based on this strategy is presented in Figure 5. This process involves the initial formation of the complex, followed by conformational adjustment of the two elements, activation of the complex through additional binding interactions and expression of the molecular chiralities of the two elements in the complex. This process describes enantioselective discrimination by all

Figure 4 Representative interactions between *S*-benoxaprofen and the AD-CSP, representing a conformationally driven chiral recognition mechanism.

classes of chiral selectors from biopolymers to derivatized amino acids.

Using Molecular Chiral Recognition to Select a HPLC-CSP

The chiral recognition mechanism presented in Figure 5 can be broken down into its separate parts if one remembers that these parts are interdependent and cannot exist apart from one another. The advantage of considering the steps independently is that it allows for the development of a system for the classification of HPLC-CSPs. If one considers that the key chromatographic step in the chiral recognition process is the formation of the diastereomeric solute-CSP complex, the current HPLC-CSPs can be broken down into five basic types on the basis of the solute-CSP bonding interactions. Using these classes and the molecular structure of the solute, one or more HPLC-CSPs can be selected for the required enantioselective separations. The resulting classes of CSPs are:

- Type I: when the solute-CSP complexes are formed by attractive interactions, such as hydrogen bonding, π - π , dipole stacking, etc., between the solute and CSP. The Pirkle type of CSPs are included in this category
- Type II: when the primary mechanism for the formation of the solute-CSP complex is through attractive interactions, but inclusion complexes also play an important role. The cellulosic and amylosic CSPs are included in this category
- Type III: when the primary mechanism for the formation of the solute-CSP complex is through the formation of inclusion complexes, wherein the sample enters a chiral cavity within the

CSP. The cyclodextrin CSPs are included in this category

- Type IV: when the solute is part of diastereomeric metal complex-chiral ligand-exchange chromatography
- Type V: when the CSP is a protein and the solute-CSP complexes are based on combinations of hydrophobic and polar interactions. CSPs based on immobilized α -acid glycoprotein, bovine and human serum albumin and enzymes such as chymotrypsin are included in this category

Conclusion

Research into chiral recognition on CSPs has expanded the original three-point interaction model into a model of molecular chiral recognition.

Introduction

The term ion chromatography (IC) does not refer to a single, specific chromatographic technique, but rather to the specialized application of a collection of established techniques. When introduced in 1975 IC referred only to the separation of inorganic anions and cations using a specific combination of ion exchange columns coupled to a conductimetric detector. Since that time, the definition of IC has expanded greatly and it can be best categorized in terms of the type of analytes separated rather than the manner in which the separation is achieved. We can therefore define IC to be:

the use of liquid chromatographic methods for the separation of inorganic anions and cations and low molecular weight water-soluble organic acids and bases.

While a range of chromatographic methods (e.g. reversed-phase ion interaction chromatography) can be used to separate these types of analytes, it is true to say that the majority of IC separations are performed by ion exchange using specialized stationary phases. In the interests of brevity, the discussion of IC will therefore be confined to ion exchange methods only. The interested reader seeking a broader coverage of the technique is referred to any of the standard texts listed in the Further Reading section.

IC methods employing ion exchange can be divided somewhat arbitrarily into two main groups, largely on the basis of historical development and commercial marketing influences. These groups of methods are referred to as 'nonsuppressed ion chromatography' and 'suppressed ion chromatography'.

Nonsuppressed IC comprises all those methods in which an ion exchange column is used to separate a mixture of ions, with the separated analytes being passed *directly to the detector*. The hardware configuration employed is shown schematically in Figure 1A, from which it can be seen that this configuration parallels the hardware used in traditional high performance liquid chromatography (HPLC). Some of the alternative names proposed for this technique are:

1. single-column ion chromatography
2. electronically suppressed ion chromatography.

The first of these names indicates that only a single chromatographic column is employed and that the eluent is not *chemically* modified prior to entering the detector, whereas the second name pertains to the fact that the background conductance of the eluent can be cancelled *electronically* by certain types of conductivity detectors. 'Nonsuppressed IC' is the most frequently used term and is recommended.

The second group of ion exchange methods consists of those in which an additional device, called the *suppressor*, is inserted between the ion exchange separator column and the detector, as shown in Figure 1B. The function of the suppressor is to modify both the eluent and the analyte in order to improve the detectability of the analytes with a conductivity detector. The suppressor often requires a regenerant solution to enable it to operate for extended periods. Methods using this hardware configuration are referred to as:

1. suppressed ion chromatography
2. chemically suppressed ion chromatography
3. eluent-suppressed ion chromatography
4. dual-column ion chromatography.

The last of these names is misleading because modern suppressors are not columns, but rather flow-through membrane devices. The term 'suppressed IC' is recommended.

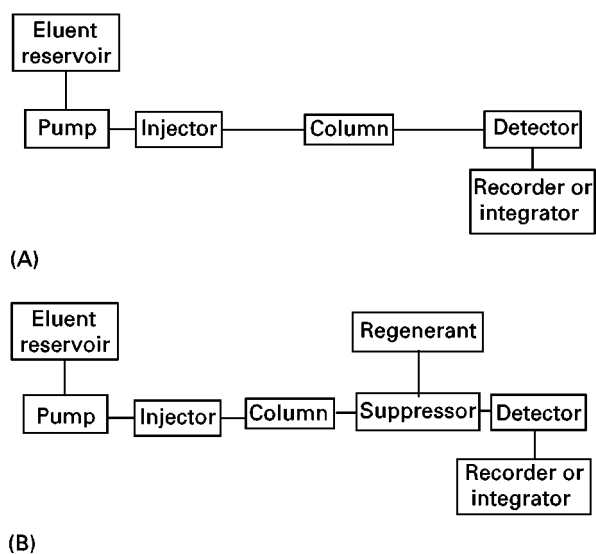

Figure 1 Block diagram showing the instrumental components used in (A) nonsuppressed and (B) suppressed IC.

Stationary Phases for IC

The ion exchange stationary phases used for IC are usually formed by chemical bonding of appropriate functional groups to a suitable substrate such as a polymer or silica. The functional groups used most commonly are sulfonates (for cation exchangers) and quaternary ammonium groups (for anion exchangers). In this respect, IC stationary phases are similar to the conventional ion exchange materials used widely throughout analytical chemistry. However, there are two important factors that differentiate the ion exchangers used in IC. The first is their ion exchange capacity. IC requires ion exchangers with low ion-exchange capacity, typically in the range 10–100 $\mu\text{equiv g}^{-1}$. This requirement can be attributed chiefly to the fact that IC was developed originally for use with conductivity detection, which introduces a preference for eluents of low background conductance in order to enhance the detectability of eluted analyte ions. The diversity of detection methods now available makes it possible to use columns of much higher ion exchange capacity, but because conductivity is still the most commonly employed detection mode, the majority of separations continue to be performed on low capacity materials. The second characteristic of ion exchangers for IC is their greatly enhanced chromatographic efficiency when compared to traditional ion exchangers.

In practice, both of the above-mentioned differentiating characteristics can be achieved by using ion exchangers in which the functional groups are confined to a thin shell around the surface of the stationary phase particle. This both reduces the number of functional groups (and hence the ion exchange capacity) and also limits the diffusion path of analyte ions, thereby improving mass-transfer characteristics and hence chromatographic efficiency. Two main approaches to synthesizing such ion exchangers can be identified. The first involves the use of only a very short reaction time during which the substrate material, i.e. either silica or a polymer such as poly(styrene-divinylbenzene) or poly(methyl methacrylate) is derivatized in order to introduce the ion exchange functional group. For example, a macroporous poly(styrene-divinylbenzene) bead immersed in concentrated sulfuric acid for less than 30 s will give a material in which sulfonic acid functional groups are confined to a very shallow depth (of the order of 20 nm) around the outside of the particle. This produces a 'surface-functionalized cation exchanger', represented schematically in **Figure 2**, in which the confinement of functional groups to the outer layer has been achieved by chemical means. Surface-functionalized anion exchangers can be produced in a similar

Figure 2 Schematic representation of the cross-section of a surface-sulfonated cation exchange resin. The negative charges represent sulfonic acid groups that are located on the surface of the resin bead. Note that the interior of the bead is not sulfonated.

manner. Historically, surface-functionalized ion exchangers have found most use in nonsuppressed IC.

The second approach to synthesis of ion exchangers for IC involves a physical process for confining the functional groups to the outer layer. These ion exchangers, known as 'agglomerated materials', consist of a central core particle, to which is attached a monolayer of small-diameter particles which carry the functional groups of the ion exchanger. Provided the outer layer of functionalized particles is very thin, the agglomerated particle exhibits excellent chromatographic performance due to the very short diffusion paths available to analyte ions during the ion exchange process. Schematic illustrations of agglomerated anion and cation exchangers are given in **Figure 3**. The central core (or support) particle is

Figure 3 Schematic representation of agglomerated (A) anion and (B) cation exchangers.

Figure 4 Formation of an agglomerated anion exchange resin using electrostatic binding. Note that the core and the latex particles are not drawn to scale.

generally poly(styrene-divinylbenzene) of moderate cross-linking, with a particle size in the range 7–30 μm , which has been functionalized to carry a charge opposite to that of the outer particles. The outer microparticles consist of finely ground resin or monodisperse latex (with diameters in the approximate range 20–100 nm) that has been functionalized to contain the desired ion exchange functional group. It is this functional group which determines the ion exchange properties of the composite particle, so that aminated (positively charged) latexes produce agglomerated anion exchangers (as illustrated in Figure 3A), while sulfonated (negatively charged) latexes produce agglomerated cation exchangers (Figure 3B). Electrostatic attraction between the oppositely charged core particles and outer microparticles holds the agglomerate together, even over long periods. **Figure 4** shows details of this electrostatic attraction for an agglomerated anion exchanger. Agglomerated ion exchangers are used most frequently in suppressed IC.

Mobile Phases for IC

Mobile phases (or eluents) for IC are similar to those used for regular ion exchange separations in that the eluent must contain a competing ion (of the same charge sign as the analytes to be separated) which serves to displace the analyte ions from the stationary phase and ultimately to elute the analytes from the column. However, eluents in IC must also satisfy the stringent requirement that they should be compatible with conductivity detection. In the case of nonsuppressed IC (in which the eluent is not involved in further reaction before reaching the detector) this means that eluent-competing ions of low limiting equivalent ionic conductance (see discussion of conductivity detection below) are required if direct conductivity detection is to be used. Aromatic car-

boxylates (such as benzoate and phthalate), aromatic sulfonates (such as toluenesulfonate) and complex ions (such as the anionic complex formed between gluconate and borate) are ideal for anion separations, whereas aromatic bases are useful for cation separations. All of these species are bulky ions having low ionic mobility (and hence low conductance) so that direct detection of more mobile analyte ions (such as chloride, sulfate, etc.) is possible using conductivity. Alternatively, indirect conductivity detection is possible using eluent-competing ions having very high values of limiting ionic conductance, such as hydronium ions for cation separations and hydroxide ions for anion separations.

Suppressed IC offers the opportunity for further reaction of the eluent before detection. The purpose of this reaction is to reduce the conductance of the eluent; in most cases acid–base reactions are used. The mechanism of eluent suppression will be discussed further below, but for the present it can be assumed that the process works best when applied to eluents comprising competing ions that can be easily neutralized in an acid–base reaction. For example, carbonate and bicarbonate (or mixtures of the two) can be used for anion separations, while dilute solutions of mineral acids can be used for cation separations.

Many cation separations cannot be achieved simply through correct choice of a suitable eluent-competing cation. Polyvalent cations show such strong electrostatic attraction to sulfonic acid cation exchangers that they can only be displaced by using concentrated eluents. This, in turn, renders conductivity detection difficult. Practical alternatives are created by the use of a complexing agent as the eluent, or by the addition of a complexing agent to an eluent that already contains a competing cation. This serves the dual purpose of reducing the effective charge on the analyte cation (and hence its affinity for the cation exchange sites) and also introduces a further dimension of selectivity between analytes that does not exist when ion exchange is the only retention mechanism in operation. The above approaches are illustrated schematically in **Figure 5**, which shows the equilibria existing between a divalent metal analyte ion M^{2+} , a complexing agent (H_2L), and an ethylenediamine (en) eluent, at the surface of a cation exchange resin. In **Figure 5A**, the eluent contains only the ligand species. Retention of the analyte ion on a cation exchange resin is moderated by the complexation effect of the deprotonated ligand, which can be said to exert a *pulling* effect on the analyte. The eluent pH determines the degree to which the ligand is deprotonated, which in turn governs the retention of the analyte. Retention is also regulated by the type and concentration of the ligand. Tartrate, oxalate, citrate

Figure 5 Schematic illustration of the equilibria existing between an analyte cation (M^{2+}), ethylenediamine (en) and an added ligand (H_2L) at the surface of a cation exchanger. In (A) the eluent contains only the ligand, while in (B) the eluent contains both ligand and ethylenediamine.

and α -hydroxyisobutyric acid are examples of typical ligands used as eluent additives.

Figure 5B shows the case where the eluent contains both a ligand and a competing cation (enH_2^+). The retention of the analyte ion, M^{2+} , is influenced by the competitive effect for the sulfonic acid groups exerted by enH_2^+ , and also by the complexation of M^{2+} by the deprotonated ligand L^{2-} . Once again, complexation reduces the effective concentration of M^{2+} and the analyte is therefore less successful in competing for the cation exchange sites. This shows that elution of the analyte results from a combination of the *pushing*, or displacement, effect of the competing cation in the eluent and the complexation, or *pulling*, effect of the complexing agent. The eluent pH influences both the protonation of ethylenediamine and the deprotonation of the added ligand, which in turn controls the degree of complex formation and hence the retention of the analyte. The type and concentration of the added ligand again play a major role in determining analyte retention. For analyte ions of similar ion exchange selectivities, the retention order closely follows the reverse sequence of the conditional formation constants for the analyte–ligand complexes.

Detection in IC

As discussed earlier, the majority of IC separations are performed in conjunction with conductivity detection. However, two further modes of detection, namely indirect UV spectrophotometry and post-column reaction with visible spectrophotometry, also find widespread use. Each of these detection modes will be described briefly.

The normal mode of operation of a detector in IC is the monitoring of a signal (due to the analyte), which appears as an *increase* above the background signal arising from the eluent alone. This is called *direct detection*, and is a useful detection mode whenever the background detector signal due to the eluent alone is small enough to be offset by the zeroing control on the detector. An alternative, namely *indirect detection*, is also possible and involves the measurement of a *decrease* in detector signal when the analyte is eluted and is generally used with eluents that give a high background signal. To function correctly, indirect detection requires that the background composition of the mobile phase must alter in the presence of the eluted analyte and it is this change, rather than a specific characteristic of the analyte itself, that is monitored. Ion exchange chromatography is the most important example of a separation mode that is suited to indirect detection.

Conductivity Detection

Conductivity detection is an important example of bulk property detection and is used commonly when the eluted analytes are ionic, for example acids and bases. However, the major use of this form of detection is for inorganic anions and cations after their separation by ion exchange chromatography. Conductivity detection is universal in response for such analytes, and the detectors themselves are relatively simple to construct and operate.

A solution of an electrolyte will conduct an electrical current if two electrodes are inserted into the solution and a potential is applied across the electrodes. It is relatively straightforward to show that the conductance of a solution, G (having the units of

microsiemens, represented by the symbol μS) is given by:

$$G = \frac{1000\Lambda C}{K} = \frac{\Lambda C}{10^{-3}K} \quad [1]$$

where Λ is the limiting equivalent conductance of the electrolyte (with units $\text{S cm}^2 \text{equiv}^{-1}$), C is the concentration of the electrolyte, expressed as equivalents per litre of solution (equiv L^{-1}), and K is the cell constant (with units of cm^{-1}) determined by the geometry of the electrodes. The conductance can be seen to be proportional to the equivalent conductance of the electrolyte and its concentration. In addition, the lower the cell constant, the higher the conductance. This occurs for cells with large surface area electrodes which are close together.

Since the conductance of the solution results from both the anions and cations of the electrolyte, we must therefore calculate conductance using values for the limiting equivalent ionic conductances (λ) of the individual anions and cations in solution. Equation [1] can now be rewritten as:

$$G = \frac{(\lambda_+ + \lambda_-)C}{10^{-3}K} \quad [2]$$

where λ_+ and λ_- are the limiting equivalent ionic conductances of the cationic and anionic components

of the electrolyte, respectively. Limiting equivalent ionic conductances for some common ionic species are listed in Table 1.

The operating principles of conductivity detection can be illustrated by considering the conductance of a typical eluent prior to and during the elution of an analyte ion. The conductance change, ΔG , produced when an anionic analyte S^- is eluted by an anionic eluent E^- , is given by:

$$\Delta G = \frac{(\lambda_{\text{S}^-} - \lambda_{\text{E}^-})C_{\text{S}}I_{\text{S}}}{10^{-3}K} \quad [3]$$

where C_{S} is the concentration of the analyte and I_{S} is the fraction of the analyte present in the ionic form. Equation [3] shows that the detector response depends on analyte concentration, the difference in the limiting equivalent ionic conductances of the eluent and analyte anions, and the degree of ionization of analyte. The last of these parameters is generally governed by the eluent pH.

Sensitive conductivity detection can result as long as there is a considerable difference in the limiting equivalent ionic conductances of the analyte and eluent ions. This difference can be positive or negative, depending on whether the eluent ion is strongly or weakly conducting. If the limiting equivalent ionic conductance of the eluent ion is low, then an increase in conductance occurs when the analyte enters the

Figure 6 Schematic illustration of the principles of direct and indirect conductivity detection.

detection cell. This detection mode is *direct*, since the analyte has a *higher* value of the measured property than does the eluent ion. Alternatively, an eluent ion with a high limiting equivalent ionic conductance can be employed and a decrease in conductance would occur when the analyte enters the detection cell. This type of detection is *indirect*, where the analyte has a *lower* value of the measured property than does the eluent ion. These detection modes are shown schematically in **Figure 6** and practical examples of direct and indirect conductivity detection are illustrated in

Figures 7 and 8. In **Figure 7A**, the weakly conducting borate–gluconate complex is used as eluent, whilst in **Figure 7B** a suppressed carbonate–bicarbonate eluent is used (see below). In contrast, highly conducting eluent ions are used in **Figure 8**, namely hydroxide (**Figure 8A**) and hydronium (**Figure 8B**) ions. Examination of **Table 1** shows that these are the most strongly conducting ions and should therefore lead to sensitive indirect conductivity detection.

Use of Suppressors with Conductivity Detection

When the conductivity detector is mounted in the usual position for a chromatographic detector, that is immediately after the column, the choice of eluent composition must also take into account the requirements for sensitive conductimetric detection. In many cases, the requirements of conductivity detection also impose constraints on the characteristics of the column used. One way to diminish this interdependence between column, eluent and detector is to insert a device between the column and detector that can chemically or physically modify the eluent. A commonly used device of this type is a suppressor, which achieves signal enhancement in conductivity detection by reducing the conductance of the eluent and simultaneously increasing the conductance of the sample band.

Figure 7 Direct conductivity detection employed in the separation of anions using (A) nonsuppressed and (B) suppressed ion chromatography. (A) A Waters IC Pak A surface-functionalized anion exchange column was used with gluconate–borate as eluent. (B) A Waters IC Pak C surface-functionalized poly(styrene-divinylbenzene) cation exchange column was used with 2 mmol L⁻¹ HNO₃ as eluent. (Chromatogram courtesy of Waters.)

The operation of a suppressor can be illustrated by considering the elution of chloride ion with an eluent of NaHCO₃. If the suppressor is capable of exchanging sodium ions in the eluent with hydrogen ions from the suppressor, the first of the reactions below occurs (reaction [I]). The HCO₃⁻ ions are converted into weakly conducting H₂CO₃, and the background conductance of the eluent is said to be suppressed. At the same time, the eluted analyte (in this case, chloride) will also undergo the second of the reactions below in the suppressor (reaction [II]).

The combined result of these processes is that the eluent conductance is decreased greatly, while the conductance of the sample is increased by virtue of the replacement of sodium ions ($\lambda_+ = 50 \text{ S cm}^2 \text{ equiv}^{-1}$) with hydrogen ions ($\lambda_+ = 350 \text{ S cm}^2 \text{ equiv}^{-1}$). The detectability of the analyte is therefore enhanced considerably.

It is important to note that suppression reactions are not limited to acid-base reactions, such as those shown in the above examples, nor are they limited to the detection of anions. Indeed, any post-column reaction that results in a reduction of the background conductance of the eluent can be classified as a sup-

pression reaction. However, the ensuing discussion of suppressor design and performance will be restricted to those which employ acid-base reactions, since these are the most widely used.

Modern suppressors are based on dialysis reactions occurring through ion exchange membranes, with the membrane being generally used as a flat sheet. **Figure 9** gives a schematic representation of the design of a typical flat-sheet (or 'micromembrane') suppressor. The eluent contacts one side of the membrane while a regenerant solution flows in a countercurrent direction on the opposite side of the membrane. In the case of the bicarbonate eluent considered earlier, the membrane would be a cation exchanger and the regenerant would be a solution containing H⁺ ions. The eluent passes through a central chamber that has ion exchange membrane sheets as the upper and lower surfaces. Regenerant flows in a countercurrent direction over the outer surfaces of both of these membranes. Mesh screens constructed from a polymeric ion exchange material are inserted into the eluent cavity and also into the cavities that house the flowing regenerant solution. The entire device is constructed in a sandwich layer configuration with gaskets being used to define the desired flow-paths. The volume of the eluent chamber is very small (< 50 μL), so band-broadening is minimal.

The mode of operation of the suppressor with a NaHCO₃/Na₂CO₃ eluent is illustrated schematically in **Figure 10A**. Sodium ions from the eluent diffuse through the cation exchange membrane and

Figure 9 Design of a micromembrane suppressor.

are replaced by H^+ ions from the regenerant, producing the desired suppression reaction. Analyte anions (e.g. chloride) are prevented from penetrating the membrane by the repulsion effect of the anionic functional groups of the membrane and therefore remain in the eluent stream. A schematic representation of the operation of this type of suppressor in the separation of cations using a hydrochloric acid eluent and a barium hydroxide regenerant solution is shown in Figure 10B.

The micromembrane suppressor combines the advantages of other suppression devices, while at the same time eliminating their drawbacks. These advantages can be summarized as:

1. small internal volume, leading to minimal band-broadening effects and hence low detection limits;
2. continuous regeneration;
3. high dynamic suppression capacity, which can be varied readily by changing the nature, concentration and flow-rate of the regenerant;
4. suitable for gradient elution with appropriate eluents;
5. resistant to many organic solvents and ion interaction reagents; and
6. a wider choice of eluent types is possible because of the high dynamic suppression capacities that can be achieved.

A recent adaptation of the micromembrane suppressor replaces the flowing regenerant solution with

Figure 10 Schematic operation of a micromembrane suppressor for eluents used with (A) anion exchange and (B) cation exchange chromatography.

water and inserts electrodes into the two regenerant compartments. This water is then electrolysed in the regenerant compartments to produce the hydronium and hydroxide ions necessary for the suppression reactions. In addition, the electric field applied to achieve the electrolysis also provides enhanced movement of ions across the membranes and thus more efficient suppression is achieved.

Indirect Spectrophotometric Detection of Anions

Indirect spectrophotometric detection is applied most frequently to the detection of anions and will therefore be discussed in this context only. When an anionic analyte S^{x-} is eluted from an ion exchanger by an eluent containing a competing anion E^{y-} , the absorbance change ΔA is given by:

$$\Delta A = \left(\varepsilon_{S^{x-}} - \frac{x}{y} \varepsilon_{E^{y-}} \right) C_S m \quad [4]$$

where $\varepsilon_{S^{x-}}$ and $\varepsilon_{E^{y-}}$ are the molar absorptivities at the detection wavelength of the analyte and eluent anions, respectively, C_S is the molar concentration of the analyte and m is the detector pathlength in cm. We see that the absorbance change measured by the detector on elution of an analyte is proportional to the analyte concentration, the cell pathlength and to the difference in molar absorptivities between the analyte and eluent anions. Equation [4] shows that indirect detection will result when the molar absorptivity of the analyte anion is less than that of the eluent anion, leading to a negative value for ΔA .

Indirect spectrophotometric detection, also called indirect photometric chromatography and vacancy detection, is a very widely used detection method in IC. Decreased absorbance accompanies the elution of analytes, but the polarity of the detector output is often reversed in order to give positive peaks on the recorder. Provided that Beer's law is followed, then linear calibration plots will result, thereby permitting sample quantification. Eluents such as phthalate, nitrate, sulfobenzoate and benzenetricarboxylate are commonly used for the separation of anions. A typical chromatogram obtained with phthalate as the eluent is shown in Figure 11.

Post-column Reaction Detection of Cations

While alkali metal and alkaline earth cations are detected routinely using conductivity detection, transition metals and lanthanoids are most commonly detected using a post-column reaction (PCR). In most cases, this involves a post-column addition of a colour-forming ligand, generally a metallochromic

Figure 11 Detection of anions using indirect spectrophotometry. A Vydac 302 4.6 IC surface-functionalized silica anion exchange column was used with 5 mmol L⁻¹ potassium hydrogen phthalate at pH 4.0 as eluent. Detection was at 285 nm. (Reprinted with permission from Heckenberg and Haddad, 1984.)

dye. Typical examples of such dyes are 4-(2-pyridylazo)resorcinol (PAR), which is used for the detection of transition metals, and 2,7-bis(2-arsonophenylazo)-1,8-dihydroxynaphthalene-3,6-disulfonic acid (Arsenazo III), which is used for the detection of lanthanoids. Both dyes react rapidly with a wide range of metal ions to form strongly absorbing complexes that facilitate sensitive detection without the need for complicated reactors or mixing devices. Figure 12 shows a typical chromatogram obtained using Arsenazo I as the PCR reagent.

Figure 12 Use of post-column reaction for the detection of lanthanoids. Separation was achieved on a Nucleosil 10SA silica-based cation exchange column using 2-methylactic acid as eluent, with post-column reaction detection with Arsenazo I. (Reprinted with permission from Wang *et al.*, 1984.)

Analytical Performance of IC

IC is now a relatively mature analytical technique and has found application across a wide range of analytes and sample types. Almost all inorganic anions can be determined using IC, as can the alkali metal cations, alkaline earth cations, the first row transition metals and the lanthanoids. However, the availability of sensitive, multielement spectroscopic analytical techniques for the measurement of cations has meant that the major focus of IC has been in the area of anion analysis. About 80% of publications on IC fall into this area.

Variation of the nature of the functional group on the stationary phase can be used as a means to manipulate separation selectivity in IC. For this reason there exists a wide range of stationary phases, and more than 150 different types of IC column are available commercially. It is therefore usually possible to identify a stationary phase suitable for most practical separations. Chromatographic efficiencies of these

columns are typically of the order of 1500 theoretical plates for a 5 cm column packed with a surface functionalized material, and 4500 theoretical plates for a 25 cm column packed with an agglomerated material.

Detection limits are dependent on the particular analyte ion and on the detection mode used. However, if one considers only conductivity detection, then detection limits of 10 ppb (for a 50 μ L injection) and 100 ppb (for a 100 μ L injection) are achievable for suppressed and nonsuppressed IC, respectively. When lower detection limits are required, on-line sample enrichment using a small ion exchange preconcentrator column can be employed, leading to detection limits which are in the ppt range.

IC has found application to a very wide range of samples, but a survey of the literature reveals that the most common application areas are environmental analysis (especially of air and aerosol samples and various natural waters), industrial analysis (such as wastewaters and process samples from pulp and paper manufacture), food and plant analysis, and clinical and pharmaceutical analysis.

Mechanisms: Normal Phase

Introduction

In normal phase chromatography the dominant interactions between the solute and the stationary phase that cause retention and selectivity are polar in nature. If dispersive interactions dominate, then the separation system is called 'reversed phase' chromatography. To comprehend the retention mechanisms involved in normal phase chromatography, it is necessary to understand the nature of the different interactive forces that are involved between the solutes and the two phases and how they occur. The retention of a solute is directly proportional to the magnitude of its distribution coefficient (K) between the mobile phase and the stationary phase which, in turn, will depend on the relative affinity of the solute for the two phases, i.e. the interactive forces between the solute molecules and the two phases. Consequently, the stronger the forces between the solute molecule and the molecules of the stationary phase, the larger the distribution coefficient and the more the solute is retained. There are only three basic types of molecular force, all of which are electrical in nature. These three forces are called 'dispersion forces', 'polar forces' and 'ionic forces'. Despite there being many different terms used to describe molecular interactions (e.g. hydrophobic forces, π - π interactions, hydrogen bonding, etc.) all interactions between molecules are the result of composites of these three basic molecular forces. Dispersion forces arise from charge fluctuations throughout a molecule resulting from random electron/nuclei vibrations. They are typical of those that occur between hydrocarbons and other substances that have either no permanent dipoles or can have no dipoles induced in them. In biotechnology and biochemistry, dispersive interactions are often referred to as 'hydrophobic' or 'lyophobic' interactions, apparently because dispersive substance such as the aliphatic hydrocarbons do not dissolve readily in water. Polar interactions arise from electrical forces between localized charges such as permanent or induced dipoles. Polar forces are always accompanied by dispersive interactions and may also be combined with ionic interactions. Polar interactions can be very strong and produce molecular associations that approach, in energy, to that of a weak chemical bond (e.g. 'hydrogen bonding'). Ionic interactions arise from permanent

negative or positive charges on the molecule and thus usually occur between ions. Ionic interactions are exploited in ion exchange chromatography where the counter-ions to the ions being separated are suited in the stationary phase. To achieve the necessary retention and selectivity between the solutes for complete resolution, it is necessary to select a phase system that will provide the optimum balance between dispersive, polar and ionic interactions between the solute molecules and the two phases.

To achieve retention, the forces between the solute molecules and the stationary phase must dominate. If the molecules are largely dispersive in character then dispersive interactions must dominate in the stationary phase and, by suitable choice of mobile phase, polar interactions are made to dominate in the mobile phase. Conversely, if the substances to be separated are largely polar or polarizable then polar interactions must dominate in the stationary phase and, by suitable choice of mobile phase, dispersive interactions must be made to dominate in the mobile phase. When polar interactions dominate in the stationary phase, historically, the separation system has been termed 'normal' chromatography. When dispersive interactions dominate in the stationary phase, historically, the separation system is said to be 'reversed phase' chromatography. Thus in normal chromatography polar interactions dominate in the stationary phase and dispersive interactions are made to dominate in the mobile phase.

The polar forces that retain solutes in normal chromatography vary in strength and somewhat in mechanism. The strongest polar forces arise from dipole-dipole interactions, where charge centres on the solute molecule interact with the opposite charge centres on the stationary phase. Compounds, such as those containing the aromatic nucleus and thus (π) electrons, are said to be 'polarizable'. When such molecules are in close proximity to a molecule with a permanent dipole, the electric field from the dipole induces a counter dipole in the polarizable molecule. This induced dipole acts in the same manner as a permanent dipole and thus polar interactions occur between the molecules. Induced dipole interactions are, as with polar interactions, always accompanied by dispersive interactions. Aromatic hydrocarbons can be retained and separated purely by dispersive interactions when using a dispersive stationary phase (reversed phase chromatography) or they can be retained and separated by combined induced-polar and dispersive interactions by using a polar stationary phase such as silica gel (normal phase

chromatography). The strongly polar hydroxyl groups inducing dipoles in the easily polarizable aromatic nucleus. A single molecule can possess different types of polarity; phenylethanol, for example, will possess both a permanent dipole as a result of the hydroxyl group and also be polarizable due to the aromatic ring. More complex molecules can have many different interactive groups.

The most common, and in fact traditional, normal phase system used in liquid chromatography consists of silica gel as the stationary phase and a mobile phase that is predominantly an alkane or a mixture containing a high proportion of an alkane. This system will be used to examine the type of interactive mechanisms that can take place in normal phase chromatography. The second solvent(s) can be more dispersive such as methylene chloride or a more polar such as ethyl acetate, *n*-propanol or even ethanol. To reduce retention, either the interactive character of the stationary phase must be reduced or the interactive character of the mobile phase increased or both. Both effects can be achieved by modifying the mobile phase. However, in normal phase chromatography, when employing mixed mobile phases, the interactions on the silica surface can become quite complex and the mechanism of retention needs some discussion. The mechanisms involved in mobile phase interactions with the solute are quite different to those involved with the stationary phase and thus, they will be considered separately.

The Nature of the Surface of Silica Gel

When the silica surface is in contact with a solvent, the surface is covered with a layer of the solvent

molecules. If the mobile phase consists of a mixture of solvents, the solvents compete for the surface which is partly covered by one solvent and partly by the other. Thus, any solute interacting with the stationary phase may well be presented with two, quite different types of surface with which to interact. The probability that a solute molecule will interact with one particular type of surface will be statistically controlled by the proportion of the total surface area that is covered by that particular solvent.

Mono-Layer Adsorption

A solvent can be adsorbed from a solvent mixture on the surface of silica gel according to the Langmuir equation for monolayer adsorption. Examples of mono-layer adsorption isotherms obtained for benzene, chloroform and butyl chloride are shown in **Figure 1**. It is seen that the surface becomes completely covered, and its interactive characteristics severely modified at relatively low concentrations of the second solvent in the mobile phase ($> 10\%$ v/v). If the second solvent is more polar, a quite different type of adsorption isotherm applies. In this case, bi-layer adsorption can take place as shown by the isotherms in **Figure 2**. Bi-layer adsorption is not uncommon and the bi-layer adsorption isotherm equation can be derived by a simple extension of the procedure used to derive the Langmuir adsorption isotherm. It should be noted that, due to the strong polarity of the hydroxyl groups on the silica, the initial adsorption of the ethyl acetate on the silica surface is extremely rapid.

The individual isotherms for the two adsorbed layers of ethyl acetate are included in **Figure 2**. The

Figure 1 Langmuir adsorption isotherms for benzene, butyl chloride and chloroform.

Figure 2 The individual and combined adsorption isotherms for ethyl acetate on silica gel.

two curves, although similar in form, are quite different in magnitude. The first layer which is very strongly held is complete when the concentration of ethyl acetate is only about 1% w/v. At concentrations in excess of 1% w/v the second layer has only just begun to be formed. The formation of the second layer is much slower and the interactions between the solvent molecules with those already adsorbed on the surface are much weaker. Assuming that the total area covered by the first layer will be the same as the area covered by the second layer, then only about one third of the layer is complete at a concentration of about 4% w/v. This is in striking contrast to the formation of the first layer which is virtually complete at an ethyl acetate concentration of 1% w/v.

From the point of view of solute interaction with the surface, it is seen that it can now be very complex indeed. In contrast to the less polar or dispersive solvents, the character of the interactive surface will be modified dramatically as the concentration of the polar solvent ranges from 0 to 1% w/v. However, above 1% w/v, the surface will be modified more subtly, allowing a more controlled adjustment of the interactive nature of the surface.

Multi-layer adsorption is also feasible, for example the second layer of ethyl acetate might have an adsorbed layer of the dispersive solvent *n*-heptane on it. However, any subsequent solvent layers that may be generated will be situated further, and further, from the silica surface and are likely to be very weakly held and sparse in nature. Under such circumstances their presence, if, in fact, real, may have little impact on solute retention.

Interactive Mechanisms on the Surface of Silica Gel in Normal-Phase Liquid Chromatography

It is clear that the interaction of the solute molecules with the stationary phase surface can be quite complex and also change with the composition of the mobile phase. There are two ways a solute can interact with a stationary phase surface. The solute molecule can interact with the adsorbed solvent layer and rest on the top of it. This is called 'sorption interaction' and occurs when the molecular forces between the solute and the stationary phase are relatively weak compared with the forces between the solvent molecules and the stationary phase. The second type is where the solute molecules displace the solvent molecules from the surface and interact directly with the stationary phase itself. This is called 'displacement interaction' and occurs when the interactive forces between the solute molecules and the stationary phase surface are much stronger than those between the solvent molecules and the stationary phase surface. An example of sorption interaction is shown in Figure 3(A). Its linear relationship is clearly demonstrated and it is seen that the distribution coefficient (which controls retention) can be adjusted to any selected value by choosing the appropriate mixture of the two solvents.

Reiterating the equation proposed by Purnell, for two solvents (A) and (B) in GC (see Figure 4):

$$V'_{AB} = \alpha(V'_A - V'_B) + V'_B \quad [1]$$

Figure 3 Different forms of molecular interaction with the silica gel surface.

The results of Katz *et al.* can be algebraically expressed in a similar form for LC:

$$K_{AB} = \alpha(K_A - K_B) + K_B \quad [2]$$

For chromatography purposes the product of the distribution coefficient and the volume of stationary

Figure 4 Graph of corrected retention volume against volume fraction of stationary phase.

phase, or stationary phase surface area, gives the corrected retention volume, i.e.:

$$V'_{AB} = K_{AB}\phi, \quad V'_A = K_A\phi \quad \text{and} \quad V'_B = K_B\phi$$

In the experiments of Katz *et al.* (see Figure 5), that validated the relationship given in eqn [4], the distribution coefficients (K) were referred to the solvent phase (mobile phase) whereas in LC it is the mobile phase composition that is changed and the distribution coefficients (K'') are referred to the stationary phase. Thus:

$$K''_{AB} = \frac{1}{K_{AB}}, \quad K''_A = \frac{1}{K_A} \quad \text{and} \quad K''_B = \frac{1}{K_B}$$

or:

$$V''_{AB} = \frac{1}{V'_{AB}}, \quad V''_A = \frac{1}{V'_A} \quad \text{and} \quad V''_B = \frac{1}{V'_B} \quad [3]$$

Substituting for the corrected retention volumes in eqn [3] for inverse phase system:

$$V''_{AB} = \frac{1}{\alpha\left(\frac{1}{V''_A} - \frac{1}{V''_B}\right) + \frac{1}{V''_B}} \quad [4]$$

Figure 5 Graphs relating distribution coefficient to solute retention for *n*-pentanol.

Simplifying:

$$V''_{AB} = \frac{V''_A V''_B}{\alpha(V''_B - V''_A) + V''_A} \quad [5]$$

Thus, when $\alpha = 0$, $V''_{AB} = V''_B$ and when $\alpha = 1$, $V''_{AB} = V''_A$.

In practice a more convenient way of expressing solute retention in terms of solvent concentration for a binary solvent mixture as the mobile phase is to use the inverse of eqn [5], i.e.:

$$\frac{1}{V''_{AB}} = \alpha \left(\frac{1}{V''_A} - \frac{1}{V''_B} \right) + \frac{1}{V''_B} \quad [6]$$

If the corrected retention volume in the pure strongly eluting solute is very small compared with the retention volume of the solute in the other pure solvent, i.e. $V''_A \ll V''_B$ which is very often the case in practical LC then eqn [6] simplifies to the simple reciprocal relationship:

$$V''_{AB} = \frac{V''_A}{\alpha} \quad [7]$$

Under these conditions the reciprocal relationship fits experimental data extremely well, particularly at volume fractions below 0.5 of the strongly eluting solute.

In addition, under these conditions the inverse will also apply, i.e.

$$\frac{1}{V''_{AB}} = \frac{\alpha}{V''_A} \quad [8]$$

Equation [8] has been validated by the results from a number of workers in the field and an example of the expected correlation is given by the curves in

Figure 6 for the two enantiomers, (S) and (R) 4-benzyl-2-oxazolidinone. The column chosen was 25 cm long 4.6 mm i.d. packed with 5 μ m silica particles bonded with the stationary phase Vancomycin (Chirobiotic V).

This stationary phase is a macrocyclic glycopeptide Vancomycin that has a molecular weight of 1449.22, and an elemental composition of 54.69% carbon, 5.22% hydrogen, 4.89% chlorine, 8.70% nitrogen and 26.50% oxygen. Vancomycin is a strongly polar stationary phase which contains 18 chiral centres surrounding three 'pockets' or 'cavities' which are bridged by five aromatic rings and thus can readily offer unique enantiomeric selectivity to a wide range of chiral substances. The column was operated in the normal phase mode using mixtures of *n*-hexane and ethanol as the mobile phase. Equation [7] is unambiguously validated by the curves relating the corrected retention volume to the reciprocal of the volume fraction of ethanol shown in Figure 6. It is also seen that an excellent linear relationship is obtained with an index of determination very close to unity.

Although silica gel was taken as an extreme example of a normal phase system, any stationary phase that is polar in nature (bonded silica or polymer based), when used with a predominantly dispersive solvent as the mobile phase, will constitute normal phase chromatography. Expressed in a slightly different way, although the interactive mechanism can be extremely complex and difficult to quantitatively predict, if the prevailing forces in the stationary phase are polar and the eluting forces in the mobile phase

Figure 6 Graph of corrected retention volume of the enantiomers of 4-benzyl-2-oxazolidinone against the reciprocal of the volume fraction of ethanol.

are predominantly dispersive then it is a normal phase system. In practice, normal phase systems are used to separate mixtures of polar substances; they are largely ineffective in separating substances that are largely or exclusively dispersive. For reversed phase chromatography, the converse applies.

Mechanisms: Reversed Phases

R. P. W. Scott, Avon, CT, USA

Copyright © 2000 Academic Press

Introduction

In the early days of liquid chromatography (LC), the most commonly used stationary phase was silica gel, which was usually loaded with water and employed with a hydrocarbon mixture such as petroleum ether as the mobile phase. To change the selectivity of the distribution system, the hydrocarbon was sometimes adsorbed on the silica, and water or an aqueous alcohol mixture was used as the mobile phase. For obvious reasons, the latter was termed a reversed-phase system. Since that time, the reversed phase has been defined in a number of different ways: in this article, it is regarded as consisting of hydrocarbon moieties chemically bonded to a silica matrix. Reversed phases are considered to exhibit predominantly dispersive interactions with any solute or solvent with which they are in contact.

The first reversed phase was synthesized by Hálasz and Sebastian in 1969 by refluxing silica with a suitable alcohol (e.g. *n*-octanol) to form the silyl ester, the hydrocarbon chain being linked to the silica by carbon-oxygen-silicon bonds. This bonding proved to be labile, as the hydrocarbon moiety was easily removed by hydrolysis, but was sufficiently stable to allow the potential of such phases to be established. The next year Kirkland and DeStefano used chlorosilane reagents to attach the hydrocarbon chain to the

silica by a silicon-oxygen-silicon bond which proved to be far more stable, at least between pH 4 and pH 8.

Subsequently, other silyl reagents, such as the silyl esters, were also shown to react with silica. Some of these reagents are now commonly used in the production of reversed phases.

Brush Phases

There are three basic types of bonded phases which are produced by the use of the mono-, di- and tri-substituted silanes: brush phases, oligomeric phases and bulk phases. For example, the monochlorosilanes (e.g. octyldimethylchlorosilane) react with the hydroxyl groups on the silica surface to produce dimethyloctylsilyl chains attached to the silica. The alkyl chains are thought to stand out from the surface like the bristles of a brush, hence the term brush phase. After reaction, the material is usually treated with trimethylchlorosilane or hexamethyldisilazane to eliminate any remaining unreacted hydroxyl groups. This procedure is called capping the bonded phase.

The extent to which the silyl groups are reacted is still a subject of some debate. It is thought that the two methyl groups next to the silicon atom of the silyl reagent hinder reaction with adjacent hydroxyl groups on the silica gel surface. Consequently, a considerable amount of unreacted hydroxyl groups will

remain between the bonded moieties even after capping. It has also been suggested that one hydroxyl group may remain situated between each bonded chain. There is certainly evidence of some polar interactions with reversed phases which, if completely covered with hydrocarbon chains, should only exhibit dispersive interactions. However, all reversed phases are predominantly dispersive in character, and it would appear that if there are any hydroxyl groups still present on the surface, their influence on retention is relatively small compared with that of the bonded moieties. However, the residual hydroxyl groups, being strongly polar, can cause separation problems under certain circumstances and thus methods that reduce their effect have been developed and will be discussed later.

Oligomeric Phases

The di-substituted silanes such as methyloctyldichlorosilanes produce oligomeric bonded phases but this involves a more complicated procedure. The silica is first reacted with methyloctyldichlorosilane to link methyloctylchlorosilyl groups to the surface. The product is then treated with water, which hydrolyses the methyloctylchlorosilyl groups to methyloctylhydroxysilyl groups with the elimination of hydrochloric acid. The hydroxy product so produced is then reacted with more methyloctyldichlorosilane, attaching another methyloctylchlorosilyl group to the previous groups. This process of alternately treating the product with the silane reagent and then water can be repeated until eight, 10 or more oligomers are linked to each other and attached to each sterically available hydroxyl group on the surface. It should be noted, however, that hydroxylation of the bonded moiety is not the only possible reaction that can take place with the water. There will be situations where it will be sterically possible for a water molecule to react with two adjacent chains and thus produce some cross-linking. However, a small amount of cross-linking would indeed strengthen the bonded system and could be advantageous.

The product is finally treated with trimethylchlorosilane, or some other capping reagent, to eliminate the last hydroxyl groups formed at the end of the oligomer. The oligomers are layered over the surface and this helps to exclude solutes from interaction with any residual surface hydroxyl groups, making the product extremely stable with almost no polar characteristics. However, due to the complexity of the synthesis (which, ideally, needs to be carried out in a fluidized bed for efficient reaction), oligomeric phases are expensive to manufacture and, consequently, are not generally available.

Bulk Phases

The trichlorosilanes (e.g. octyltrichlorosilane) bond dichlorosilyl moieties to the surface and, in the presence of water, or if water is added, cross-linking occurs and a polymeric hydrocarbon stationary phase is produced. The same procedure can be used as that in the synthesis of oligomeric phases. The silica can be alternately treated with water and the trichlorosilane reagent. Layers of bonded phase are built up on the surface with extensive cross-linking, which produces a multilayer polymeric phase that has been termed a bulk phase. The bulk phases are almost as popular as the brush phases as they tend to have a higher carbon content (more organic material bonded to the surface) and thus provide a greater retention and selectivity. Bulk phases have about the same stability to aqueous solvents and pH as the brush phases.

The residual polarity of the bonded phase arising from the unreacted hydroxyl groups can cause peak tailing under certain circumstances. Consequently, it would be highly desirable to remove them or, at least reduce their effect on solute retention, particularly when present in brush phases. This was partly achieved by Kirkland who used reagents with larger base side chains (e.g. dipropyloctylchlorosilane as opposed to dimethyloctylchlorosilane) which linked a dipropyloctylsilyl group to the surface silicon atom. The larger propyl groups close to the silica surface tended to screen the adjacent hydroxyl groups sterically and thus significantly reduced their interactive availability. This, in turn, reduced their effect on retention. All three types of reversed phase are fairly stable, at least between pH 4 and pH 8 and at ambient temperature. The phase stability decreases as the temperature is raised: to some extent this can be overcome by introducing a phenyl group in the hydrocarbon chain.

Both brush and bulk reversed phases are commonly used in liquid chromatography, but the brush phase, although providing less retention for a given stationary phase loading, appears to be easier to manufacture in a reproducible form. Reversed phases are produced commercially with a range of chain lengths. Commonly available brush reversed-phase chain lengths range from a single carbon (using trimethylchlorosilane or ester as the reagent) to C₃₀.

In general, the retention of a solute increases linearly with the carbon content of the reversed phase, as shown in **Figure 1**. It is seen, however, that the brush phases and the bulk phases fall on different lines. The bulk phases both contain C₁₈ chains but with different degrees of reaction; the ODS has a significant number of the hydroxyl groups unreacted. It appears that the hydrocarbon chains in the bulk

Figure 1 Graph of retention volume (V') against carbon content (%w/w). ODS and ODS2, C_{18} bulk-reversed phases. RP2, RP8 and RP18, C_2 , C_8 and C_{18} brush-reversed phases.

material are more available to the solute than in the brush material, indicating that in the bulk phases, the polymeric material might have a fairly open structure. The brush phases were fully reacted (although, as already discussed, some hydroxyl groups will still be present) and it is seen that retention increases linearly with the chain length.

Reversed phases with long chains and high retention properties, although apparently desirable due to their high selectivity, are not always appropriate. For example, the strong dispersive interactions exhibited by these phases can cause irreversible retention of proteins and other biopolymers, usually accompanied by denaturation. As a result, the C_2 and C_4 phases are very popular in the biotechnology field. In con-

trast, the separation of complex mixtures of stable compounds such as essential oils, fatty acids, pesticides, herbicides and the host of other mixtures produced and used in industry today are best achieved using the longer chain materials.

Particle Shape and Size

Originally, reversed phases were produced from irregularly shaped particles of silica which, after air jet grinding was introduced, were well rounded but not perfectly spherical in shape. The silica was cleaned by various washing procedures to remove heavy metals that were thought to cause peak tailing. This material, when converted to a reversed phase, packed well and provided columns of the expected efficiency (*c.* $L/1.6dp$, where L is the column length and dp the particle diameter). The introduction of spherical silica, which was claimed to pack more easily and was manufactured from silica of greater purity, has now largely replaced the irregular silica. In fact, the retentive properties and efficiencies derived from the spherical silica do not seem to be strikingly different from those produced from irregular silica, if packed properly.

Reversed phases are mostly produced in four particle sizes: 3, 5, 10 and 20 μm . The 3 μm material is usually provided in columns 3 or 5 cm long, giving about 5000 and 8000 theoretical plates respectively. These columns can be operated at 1–2 mL min^{-1} and thus provide fairly fast separations. The 5 μm packings are usually supplied in columns 5 and 10 cm long and the 10 μm particles in columns 10 and 20 cm long. A column 20 cm long packed with 10 μm particles can be expected to provide efficiencies of about 12 000 theoretical plates at a flow rate of 1 mL min^{-1}

Figure 2 The adsorption isotherms for some aliphatic alcohols on a reversed phase. 1, Butanol; 2, propanol; 3, ethanol; 4, methanol. (Reproduced with permission from Scott, 1993.)

Figure 3 The adsorption isotherm of acetophenone between a reversed phase and an aqueous solvent mixture containing 40.4%w/v acetonitrile. (Reproduced with permission from Scott and Kucera, 1977.)

and is thus very useful in the separation of complex mixtures. The 20 μm packing is almost exclusively used for preparative columns.

Reversed-phase columns are slurry packed, usually employing a methanol–water mixture or ethanol as the packing solvent. There are many proprietary solvent mixtures used in packing reversed-phase columns and the technique has assumed an artificial cloak of mystery. The important aspect of packing is to use a wetting agent (there are many that can be

used successfully) to ensure the particles do not clump together in the packing solvent but are completely dispersed. This can be checked under a low powered microscope. The packing, dispersed in the solvent and wetting agent (often by sonic vibration), is packed by suddenly applying about 8000 psi pressure to the particle dispersion contained in a high pressure reservoir, forcing the slurry through the column; the packing is retained by an appropriate terminal frit.

Interactions on the Surface of Bonded Phases

Solute interactions with the stationary phase in LC, differ from those in gas chromatography (GC) due to the preponderance of solvent that is concurrently interacting with the surface. In fact, in LC, the solute and the solvent interact in exactly the same manner with the stationary phase, but the concentration of the solvent is many orders of magnitude greater than that of the solute. Consequently, an equilibrium arises between the solvent and the stationary phase which is perturbed by the passing presence of the solute. It has been well established that solvents are adsorbed on the surface of a bonded phase as mono- or binary layers according to the Langmuir adsorption isotherm. The equation for the Langmuir adsorp-

Figure 4 Alternative forms of solute interaction with the surface of a reversed phase. (A) Surface incompletely and (B) surface completely covered with solvent molecules. Open circles, alcohol; filled circles, solute.

tion isotherm of a monolayer is as follows:

$$\alpha = \frac{ac}{b + ac}$$

where α is the fraction of the surface covered by the solute, c is the concentration of the solute in the mobile phase, and a and b are constants.

At high concentrations α becomes unity and the surface is completely covered with the more strongly adsorbed solvent. An example of the monolayer adsorption isotherms of some aliphatic alcohols from their aqueous solutions is shown in Figure 2.

It is seen that the most polar alcohol, methanol, does not saturate the surface until the methanol concentration of the mobile phase is in excess of 30%. In contrast, the surface is completely covered with the more dispersive alcohol, butanol, when its concentration is less than 5%.

In reversed-phase chromatography, aqueous solutions of organic solvents such as methanol and acetonitrile are usually employed as the mobile phase. Consequently the solute molecules will also exhibit Langmuir-type adsorption isotherms when interacting with the surface of a phase. An example of the adsorption isotherm of acetophenone between a mobile phase containing 40.4% v/v acetonitrile (the concentration at which the reversed phase is completely wetted by the solvent) and the phase surface covered with adsorbed solvent is shown in Figure 3.

Only the initial approximately linear part of the isotherm is shown, indicating that the adsorption process is similar to that exhibited by the mobile-phase solvent. It is clear that the solute can interact with the reversed phase in a number of ways depending on the equilibrium conditions that exist between the solvent in the mobile phase and the surface. The alternative forms of interaction are depicted in Figure 4.

In the first case, where the concentration of the solvent is insufficient to cover the entire surface, the solute can interact directly with the uncovered surface, interact with the solvent molecules covering the surface or displace a solvent molecule and interact directly with the surface. All these alternatives will occur during the passage of the solute through the column. In the second case, where the concentration of the solvent is sufficient to ensure that the surface is covered with the solvent molecules, the solute can only interact with the solvent molecules covering the surface, or displace a solvent molecule and interact directly with the surface. The latter can only occur if the interaction energy between the solute and bonded moiety is greater than that between the solute and the adsorbed solvent.

It is seen that the interaction of the solute with the reversed phase can be quite complex and will depend not only on the nature of the solute itself, but on both the nature and concentration of the solvent in the mobile phase. It is clear that a ternary solvent system would be even more complex, and if the solvent composition is changed during development (as in gradient elution) the distribution system at any particular concentration, although possible to calculate from adsorption isotherm data, can be a very complicated procedure indeed.

Applications

Reversed phases are the most commonly used stationary phases in contemporary LC and are employed in over 65% of all analytical applications. They are largely used with water as a component of the mobile

phase, in binary, ternary and occasionally quaternary mixtures with aliphatic alcohols, nitriles and ethers, e.g. methanol, acetonitrile and tetrahydrofuran. They are also used with ion-pairing reagents in ion chromatography where the reagent is adsorbed as an interactive layer on the surface of the stationary phase. The mechanism of ion-pairing reagents is complex and will be discussed elsewhere.

Reversed phases are used in industrial product quality control, environmental testing, clinical analyses, biotechnological assays, forensic examination and many research programmes. Numerous examples of the use of reversed phases are included elsewhere in this book: some will be given here to illustrate the types of separation possible using predominantly dispersive interactions with the stationary phase. An example of an environmental or forensic type of application is given in **Figure 5**. The separation was carried out on an octadecyl bonded phase using a 50% v/v methanol–water mixture as the mobile phase. The selectivity of the dispersive stationary phase is clearly demonstrated, the more polar materials having strong polar interactions, with the strongly polar mobile phase being eluted first. In contrast, the relatively strong dispersive interactions of the monosubstituted toluenes with the reversed phase cause them to be eluted last. It is also seen that the explosive components are well resolved and detected quantitatively (mostly at the sub-microgram level) with no difficulty. Some samples can be separated by

weaker dispersive interactions using reversed phases with shorter chains. An example of the use of a C_8 reversed phase for the separation of a number of carbamate and urea pesticides is shown in **Figure 6**. The separation is achieved using a gradient that starts with a highly polar binary aqueous mixture containing only 18% v/v acetonitrile to a moderately polar solvent mixture containing 65% v/v acetonitrile. It is seen that excellent separation is obtained in only 12 min.

As discussed earlier, the use of dispersive interactions to separate biologically labile compounds demands the use of short chain length reversed phases to prevent irreversible adsorption and/or solute denaturation. An alternative approach is to use one of the polar bonded phases in a manner where the dispersive interactions dominate but not sufficiently to cause strong adsorption. The amino or diol polar phases have been used in this manner to separate protein and protein-like materials and an example is given in **Figure 7**. It is seen that water containing no solvent is used as the mobile phase, which virtually completely negates the polar interactive capability of the polar stationary phase. The only significant interactions remaining are those with the dispersive moieties of the bonded material. This results in only weak interactions between the solutes and the stationary phase and the separation is attained without significant tailing (a symptom of strong adsorption) or denaturation.

Figure 7 The separation of some proteins on a polar phase used in the reversed phase mode.

Due to limited pressure available in liquid chromatographs, which is not constrained by pump design but rather by other parts of the chromatograph (in particular the sample valve), the reduction in particle diameter of a column packing is limited in practice. Small particles can only be used with shorter columns, which results in reduced separation times but not an increase in the attainable column efficiency. The shorter columns packed with very small particles also produce extremely small peak volumes that place serious constraints on the sample system and in particular the detector sensor cell. Although in the research laboratory, particles having diameters less than 1 μm may well be developed and their efficacy demonstrated, their general use in analytical laboratories will be very limited for some years to come. Due to the versatility and wide range of operating variables available, difficult separations are more easily achieved by using procedures other than by reducing the particle size to a level where practical difficulties become paramount.

Reversed phases are probably the most effective and popular stationary phases in use today. However, stationary phases employing bonded silica may well

not be the best form of reversed stationary phase to use in the future. The great disadvantage to silica-based stationary phases is their instability in aqueous solvents, particularly at extreme pH. The future stationary phases that will be used in LC are more likely to be some form of macro-reticulated polymeric materials that have been developed and are already quite widely used. These polymeric particles can be prepared with significant surface area and porosity and are extremely inert and stable in aqueous solvent mixtures at the extremes of pH. They can also be prepared with a wide range of polarities linking different chemical groups to their surface and by using different polymer bases.

Mechanisms: Size Exclusion Chromatography

Introduction

Size exclusion chromatography (SEC), also known as gel permeation chromatography (GPC), is a particularly valuable tool in the measurement of the molecular weights and molecular weight distributions of polymers. There are a number of variations on the basic technique to accommodate the requirements of different polymer types and to elicit additional information. This article seeks to describe the basic technique with particular comment to the often under-appreciated limitations together with detailed comment on the main variations to the basic technique. The relationship between SEC and other techniques for polymer molecular weight techniques will be summarized.

As examples of the technique, Figure 1(A) is an overlay plot of the computed molecular weight distributions for a range of extrusion grades of polystyrene from various producers and Figure 1(B) illustrates the variation in molecular weight for a series of poly(methylmethacrylate) (PMMA) materials polymerized under different conditions. The descriptions in this article will normally relate to the general practice in the use of SEC with polymers soluble in the normal organic solvents. Some comments will also be made on the aqueous-based SEC of processable polymers. Biopolymers, such as polypeptides and proteins are also examined using SEC, but the consideration of appropriate buffers and column packings has not been considered appropriate for separate comment.

SEC – The Basic Technique

SEC is a specific form of liquid chromatography where the only fundamental difference is in the column packing and the separation mechanism. However, the particular requirements of SEC are somewhat different to most other forms of liquid chromatography giving rise to various aspects in the choice of instrumentation, data handling and general practical philosophy.

SEC Columns and the Separation Mechanism

In SEC, the polymer molecules are separated as a function of their size in solution. The column pack-

ings are porous and the separation is achieved according to the degree of access of the polymer molecules to the pores.

The solvent in the column packing pores can be considered as the stationary phase and the interstitial solvent as the mobile phase. A distribution coefficient is established by which the time spent in the pores, or stationary phase, is dependent upon the solvated size of the polymer molecules and on the pore geometry. Since the larger molecules are more restricted in the pore volume available to them, the larger molecules spend less time in the stationary phase and are eluted first; smaller molecules are effectively retarded and elute later.

It is fundamental to SEC that no other separation mechanism (e.g. adsorption) is occurring. As a consequence, the maximum elution volume available to achieve separation is the total pore volume. Molecules which are so large that they are totally excluded from the pores will elute at a volume corresponding to the interstitial or 'void' volume while molecules which can permeate all of the pores will elute at a volume corresponding to the void volume plus the pore volume. Anything eluting at a greater volume than this must be retarded by some additional mechanism.

With consideration to the above requirements, the materials used for SEC column packings are mainly selected for their pore geometry and lack of other interaction with the polymer molecules. In many solvent systems, the potential for adsorption limits the applicability of inorganic packings and polymeric packings are the more usual choice. The bulk of all SEC work with synthetic polymers is carried out using column packings produced from polystyrene, cross-linked with divinylbenzene. In the production of these materials, the pore geometry is manipulated to give variation in pore size and hence 'tailored' to suit particular molecular mass ranges.

In addition to pore size and inertness, the normal chromatographic relationships between packing size and efficiency are applicable but, as noted later, there are limitations to using too small a packing size with the higher molecular weight polymers.

SEC column packings are normally produced with a limited polymer molecular weight applicability but it has been normal practice to use a number of different columns (with specific pore sizes) in series to give an acceptably wide molecular weight range. Typically, to cover a molecular weight range of 2000 to 2 000 000, a bank of columns such as 1×10^3 Å, 1×10^4 Å, 1×10^5 Å and 1×10^6 Å would be used.

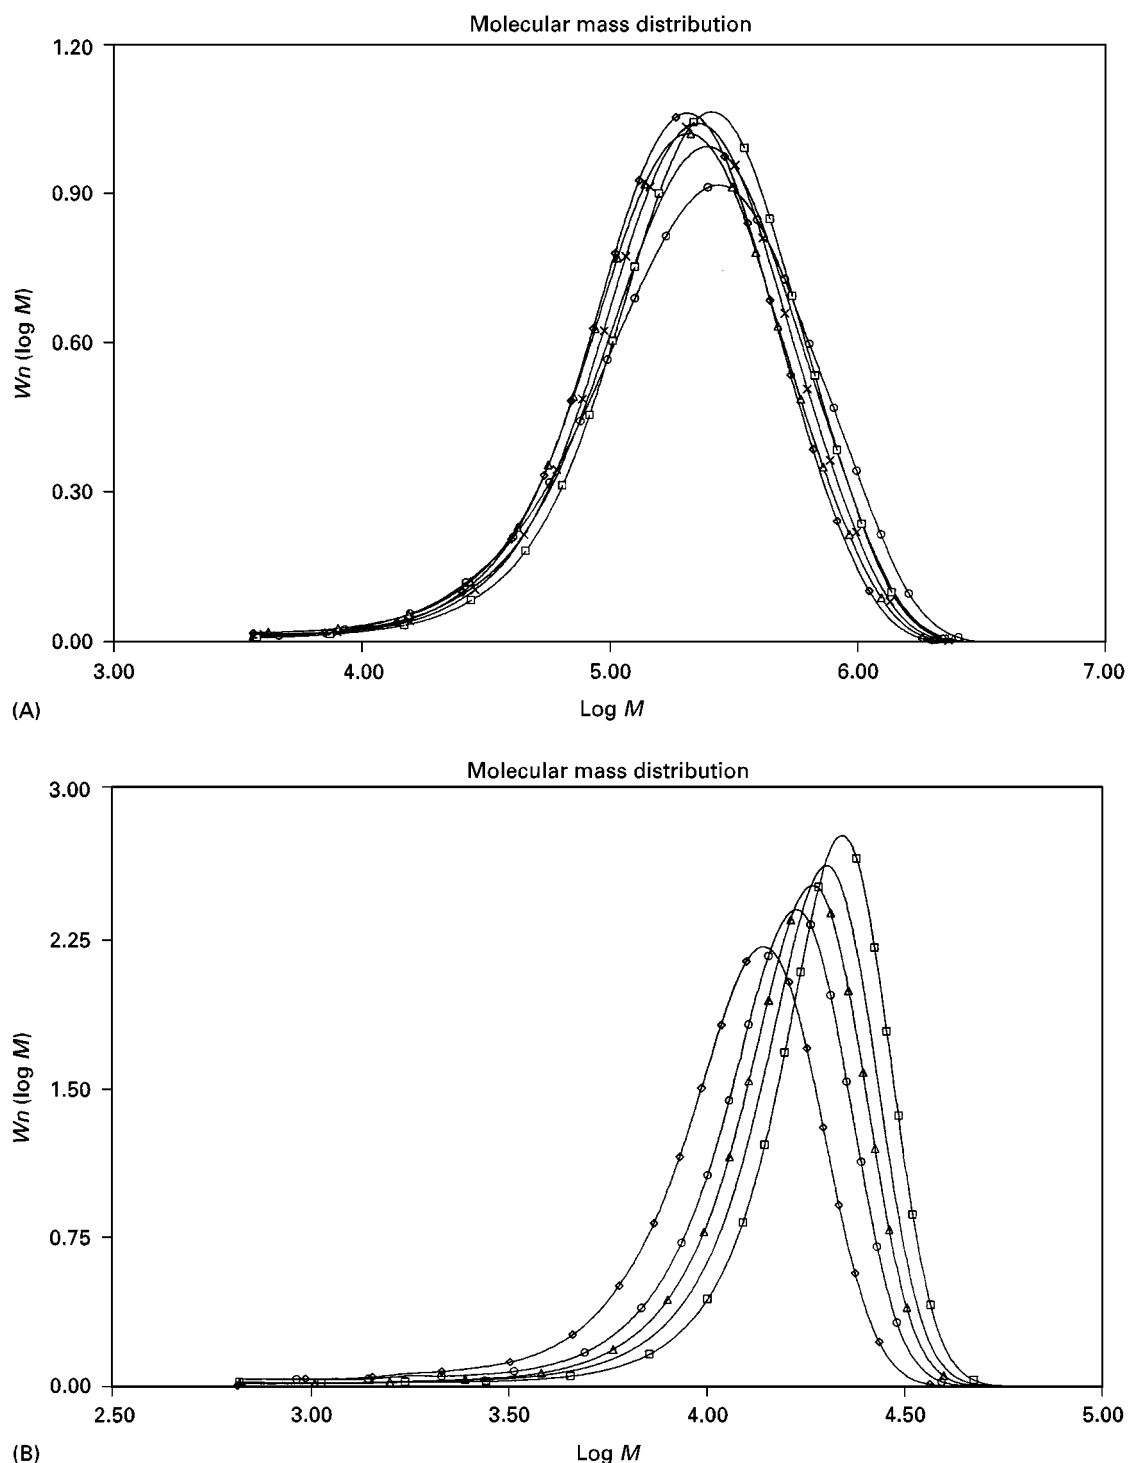

Figure 1 An overlay plot of the computed molecular weight distributions for a range of extrusion grades of polystyrene from various producers.

(The identification of pore size expressed in angstroms is common practice but potentially misleading, since the dimension refers to maximum extended polymer chain length, rather than actual pore size.)

There is potential for using an inappropriate combination of column packings and it is now becoming more common to obtain single columns which the manufacturer has filled with different porosity packings to give a wide molecular weight range. This

'mixed-bed' approach also gives an optimal combination of packing porosities such that a 'linear' calibration is obtained (see later). Even with the mixed-bed approach, a number of columns will normally need to be combined to achieve an acceptable peak capacity.

Efficiency and Resolution

The factors generally affecting column efficiency in other forms of liquid chromatography also apply to SEC, and column efficiency is calculated and expressed in the normal manner. The efficiency as calculated for a specific low molecular weight compound (e.g. an added solvent) will normally be higher than for a truly monodisperse polymer and the efficiency is normally reported for a solvent peak.

The resolution of two given monodisperse components can be sensibly expressed in a similar manner as for other forms of liquid chromatography but in SEC it is also possible to define a 'specific resolution' which relates to the theoretical resolution of two monodisperse polymers having one decade difference in molecular weight. The specific resolution will be dependent upon the gradient of the calibration (as expressed by log molecular weight versus elution volume). If the calibration is linear (on the log molecular weight scale) then the specific resolution will be constant across the molecular weight range.

Column Packing Size and Shear Effects

For some time the normal column packing particle size available has been around 10 μm but, in common with other forms of liquid chromatography, there has been a trend towards increasing the efficiency by producing smaller particle size packings. However, when working with high molecular weight polymers, the higher linear flow velocity associated with the smaller packing sizes can cause shear degradation of the polymer and the particle size must be selected to suit the molecular weight of the sample polymer. The 10 μm material is appropriate for a very wide range of molecular weights but additional efficiency can be obtained by using 5 μm packing for polymers with moderate molecular weights (ca. 10 000 to 100 000) and 3 μm packings can be used for lower molecular weights. For very high molecular weight polymers (ca. > 2 000 000) the use of larger packing size (e.g. 20 μm) should be considered. Where there is potential for shear degradation, lower solution concentrations and lower flow-rates can also reduce this unwanted effect.

SEC Pumps and Flow-Rate

Normal isocratic HPLC pumps are used for SEC work but the requirements for good control of the

flow-rate are probably more severe. Since in SEC, it is an envelope of a multitude of different molecular weight peaks that is being measured, it is not possible to set an identification window and any small variation in flow rate will produce an error in the molecular weight calculation. Variation in flow-rate can be allowed for by the use of an internal marker. For a typical polystyrene, a deliberate correction of the flowrate by 0.2% produces a variation in the calculated weight average molecular weight from 308 000 to 320 000; a variation of approximately 4%.

SEC Concentration Detectors and Sample Concentration

A number of detector types for specific additional information will be considered later but the most basic SEC application requires a concentration detector to monitor the polymer as it emerges from the column.

The most common form of concentration detector encountered in SEC is a differential refractive index (DRI) detector. These detectors are a cost-effective option which are nearly universal in application but they have limited sensitivity and require a very good temperature control. Since SEC is normally used to look at bulk components (rather than trace components), the poor sensitivity is not normally a problem but some difficulties may be encountered where the differential refractive index for the polymer/solvent combination is so small that baseline noise becomes significant.

The other universal detector used in SEC is the ELSD (evaporative light scattering detector, also known as an evaporative mass detector). These units involve atomization of the eluent into a steady flow of inert gas where the solvent is removed and the remaining solute particles are detected by the light scattering they induce. It is important to distinguish between these ELSD and the light scattering from solutions considered later. The ELSD is more expensive than DRI detectors and there are potentially high running costs for the large amount of inert gas consumed. However, they are less affected by any variation in solvent composition or temperature and are more universal in the size of the response regardless of chemical composition of the polymer.

Figure 2 is a schematic diagram of a commercially available evaporative light scattering detector.

Other types of HPLC detector (such as ultra-violet, infrared or radiochemical) are also used for SEC but are more restricted in applicability and are used more as selective detectors to pick out specific components. There are latter comments with regard to the SEC of copolymers.

Figure 2 A schematic diagram of a commercially available evaporative light scattering detector. Printed with the permission of Polymer Laboratories Ltd, Church Stretton, Shropshire, UK.

Detector Response to Low Molecular Weight Components

The differential refractive index for a polymer/solvent combination is normally independent of molecular weight at high molecular weight. However, while it is generally known that the refractive index detector response varies with low molecular weight polymers this variation is commonly ignored. As a consequence, SEC results for polymers containing low molecular weight material often do not give an appropriate consideration to the low molecular weight components; this has important implications for many legislative requirements for defining the proportion of low molecular weight material present.

The variation in refractive index response with molecular weight is presumed to be due to the increasing influence of end groups and it seems probable that there are similar effects with most other detector types. For the evaporative light scattering detector, there is similarly the possibility that the more volatile components are lost with the solvent.

SEC Calibration and Data Handling

For SEC a calibration must be obtained by running polymers of known molecular weight. The more usual practice is to run a series of calibrants of very narrow molecular weight distribution (often described as being monodisperse) and known peak molecular weight (M_p) and obtain a calibration of log

M_p versus elution volume. Alternatively, there are procedures for using broad molecular weight distribution calibrants, where the molecular weight distribution is well defined.

In practice, the most commonly used calibrants consist of narrow distribution polystyrenes, and a wide range of these is commercially available. A small range of other polymer types of narrow distribution calibrants is also available but usually with a restricted molecular weight range. The availability of well-defined broad molecular weight distribution calibrants is extremely limited.

The log M_p versus elution volume calibration is usually expressed by an equation which can be a simple linear expression or a polynomial. The software will frequently allow an excellent fit by using a high order polynomial but it is questionable whether an order of three should ever be exceeded. In practice, reasonable good fits are normally obtained using first, second or third order curves but even for third order fits, the potential for variation at low molecular weight, affecting the high molecular weight end of the distribution, is intrinsically present.

The calculation of molecular weight averages and plotting molecular weight distributions from a sample chromatogram and calibration is complex and the use of laboratory computers was introduced early to SEC. However, automatic data handling has often led to inappropriate manipulation of the data and care is always required. The whole chromato-

Figure 3 Chromatograms of four solutions containing 10 narrow molecular weight distribution polystyrene calibrants.

gram envelope for the polymer is used in the calculations and any minor variation in baseline placement or integration limits at the extreme ends of the distribution is likely to have significant effects on one of the calculated molecular weight averages.

Measurement of Molecular Weight Averages

All synthetic polymers and many natural polymers have a molecular weight distribution and it is usual to calculate average molecular weights from these distributions. Although there are a considerable number of averages that have previously been used, the most common are the number average, M_n , weight average, M_w , and the z -average, M_z . These are defined as follows:

$$M_n = \sum(N_i \cdot M_i) / \sum N_i$$

$$M_w = \sum(N_i \cdot M_i^2) / \sum(N_i \cdot M_i)$$

$$M_z = \sum(N_i \cdot M_i^3) / \sum(N_i \cdot M_i^2)$$

where N_i is the number of molecules of molecular weight M_i .

The molecular weight is generally calculated from the normalized chromatograms by dividing the chromatogram into slices. The area of each slice (b_i) is measured and the molecular weight (M_i) determined from the calibration curve. The molecular weight averages are then calculated as follows:

$$M_n = \sum b_i / \sum (b_i / M_i)$$

$$M_w = \sum (b_i \cdot M_i) / \sum b_i$$

$$M_z = \sum (b_i \cdot M_i^2) / \sum (b_i \cdot M_i)$$

In practice, the weight average molecular weight generally corresponds to a molecular weight near the maximum of the chromatogram and the repeatability of the measurement from SEC is normally better than for the other averages. The number average molecular weight is sensitive to minor variations at the low molecular weight end of the distribution while the z -average is more influenced by differences at the high end of the distribution.

The term 'polydispersity' is often used as a measure of the width of a molecular weight distribution and is usually the ratio of the weight average to number average molecular weights (M_w/M_n).

Figure 3 shows an overlay of the chromatograms for four solutions containing a total of ten individual, narrow molecular weight distribution polystyrene calibrants and Figure 4 shows the log (molecular weight) versus retention volume calibration derived from these chromatograms.

Figure 5 shows an overlay of one of the chromatograms for one of the above calibrant solutions and a broad molecular weight distribution polymer of unknown molecular weight and Figure 6 shows the calculated molecular weight averages and molecular distribution obtained from applying the calibration to the molecular weight computation with this chromatogram.

In Figure 6, the frequency is expressed as weight fraction per unit of log (molecular weight), $Wn(\log M)$.

The Universal Calibration Procedure

When a polystyrene calibration is applied for the measurement of a polymer other than polystyrene, the results can be expressed as the polystyrene equivalent molecular weights or it might be possible to

Figure 4 Log (molecular weight) versus retention volume calibration derived from chromatograms shown in Figure 3.

apply a mathematical correction to describe the true molecular weights. The most common mathematical correction, for polymer type, is known as the Universal Calibration Procedure and is based on the early empirical observation that if the calibration is expressed as the log of the product of molecular weight and intrinsic viscosity versus elution volume, then a common calibration is obtained for many polymer types (if the simple log molecular weight vs. elution volume calibrations are plotted, a series of related calibration plots are obtained).

The intrinsic viscosity factor in the universal calibration allows for the variation in solvation between

different polymers. This difference in solvation is closely related to solution viscosity measurements and it is the K and α values from the Mark-Houwink-Sakurada equation which are used in this correction.

The K and α values for both the calibrant and sample polymer types in the solvent used and at the measurement temperature must be known. In practice, the literature contains a lot of data on measured K and α values and if appropriate values are selected with care, the computed molecular weight data can be close to the true values. However, it must be appreciated that the nature of any branching can

Figure 5 Overlay of one of the chromatograms for one of the above calibrant solutions and a broad molecular weight distribution of unknown molecular weight.

Figure 6 Calculated molecular weight averages and molecular distribution obtained from applying calibration to molecular weight computation with chromatogram in Figure 5. Frequency is expressed as weight fraction per unit of log (molecular weight), $Wn(\log M)$.

have a significant effect on these values and in the literature values were frequently obtained many years ago when the polymer structure might have been somewhat different to common materials today.

The Universal Calibration procedure appears to be appropriate for polymers which have a normal random coil configuration in solution but fails for any polymer type which has any structured conformation in solution. The philosophy behind this approach is also used in combined SEC-viscosity measurements (see later).

High Temperature SEC

In the early days of SEC, it was appreciated that this was a technique that could be used at high temperature and be applied to polymer types for which there was no room temperature solvents, particularly polyethylene and polypropylene, and appropriate commercial instrumentation was soon introduced. Despite this early appreciation of the value of high temperature SEC, it remains a difficult application.

High temperature SEC is carried out either to be able to dissolve the polymers of interest, as with polyolefins, or to reduce the viscosity of the solvents. In practice, SEC of polyolefins requires a minimum temperature of 140°C and is usually carried out with chlorinated aromatic solvents; the SEC of polyesters (such as PET) or polyamides is carried out using phenolic solvents at temperatures of at least 110°C, while SEC with polar solvents, such as dimethylformamide is carried out at temperatures around 80°C. In addition, some SEC is carried out at raised temper-

ature to enhance the efficiency (particularly aqueous SEC).

Polyolefins tend to come out of solution if there is a cool spot in the total instrumentation, which is the main complication with these polymer types but there is potential for other temperature incompatibilities (e.g. temperature cycling on an RI detector). In addition, solvents at high temperature are likely to swell polymer components in the SEC instrumentation (e.g. pump seals) and it is desirable to dedicate the instrumentation to specific applications. With the high temperature SEC using phenolic or polar solvents, the main complications are not necessarily directly related to the high temperature.

SEC with Polar Solvents

Polar polymers normally require the use of polar solvents such as dimethylformamide (DMF), dimethylsulfoxide (DMSO), N-methylpyrrolidine (NMP) or dimethylacetamide (DMAC). Work with these solvents is carried out at raised temperatures (e.g. 80°C), to reduce the viscosity, and it is normal practice to add salts to try and suppress interactions other than SEC. SEC of polyesters and polyamides can be carried out at ambient temperature using fluorinated alcohols but the solvents are excessively expensive and of questionable toxicity.

Although the standard polystyrene-based columns are normally used for SEC with polar solvents, the polystyrene calibrants may not be applicable and the use of alternative calibrant polymers such as polyethyleneglycol/polyethyleneoxide or polymethylmethacrylate is common.

SEC with Phenolic Solvents

As noted above, the SEC of polyesters, such as polyethylene terephthalate and many polyamides is often carried out using phenolic solvents at temperatures of around 110°C or 120°C. Typical solvents are *m*-cresol or *o*-chlorophenol. It is the unpleasant nature of the solvents which is the main problem with these SEC applications but in general the problems of high temperature SEC increase with temperature.

In the author's laboratories, the SEC of polyesters appears to be reasonably straightforward but the weak DRI detector response for polyamides is problematic.

Aqueous SEC

The SEC of polymers in aqueous media has generally been considered more complex due to the frequent need for complex buffer selection and to the requirement for hydrophilic column packings. In the early days of SEC, the hydrophilic column packings available gave significant problems but this appears to have been largely overcome with the advent of high efficiency hydroxymethacrylate packings.

For most water-soluble polymers, it remains necessary to select pH and ion concentration suited to the polymer type of interest and it is not practical to have standard conditions for aqueous SEC work. However, it is usual to raise the temperature to obtain enhanced efficiency.

SEC with Selective Detectors

Fixed wavelength ultra-violet or infra-red detectors are used with a 'universal' detector (such as DRI) and appropriate software to obtain information on how specific chemical groups vary through the molecular weight distribution. However, it should be noted that appropriate spectral windows for the solvent are required to allow this approach to be used and the presence of antioxidants or other additives, in the solution, can be a problem.

Modern diode array detectors can be used to obtain more complex information where applicable.

SEC with FTIR

It should be possible to use the rapid scanning capability of Fourier Transform Infra-Red spectrophotometers to obtain very detailed information on chemical composition but the lack of spectral windows is a severe limitation. Direct combination of SEC and FTIR has been used with tetrachloroethylene as the solvent (which has a very simple infra-red spectrum) to examine ethylenevinyl acetate (EVA) copolymers and a similar direct combination is used for polyolefin samples.

Solvent Removal Approaches

Since the main problem with direct combination of SEC with FTIR is the lack of spectral windows in the solvent, a number of researchers have studied approaches to remove the solvent prior to the FTIR examination.

Laboratory Connections Inc. have developed approaches which use either warm gas or ultra-sonication and vacuum to remove solvent from the atomized eluent and deposit the fractionated material as a thin annulus on a germanium disc. The germanium disc is then transferred to a matching rotating stage located in the infra-red instrument and spectra are recorded as the disc is rotated to mimic the chromatogram. Specialist software allows complex manipulation of the chromatography and spectroscopic data. The quality of spectra that can be obtained without any requirement to overload the chromatographic system is very good and this technique can be used for most SEC approaches and the only real limitation is the potential for losing low molecular weight material with the solvent.

SEC with Light Scattering Detection

Light scattering has long been used as a stand-alone technique for the absolute measurement of the weight average molecular weight of polymers. The classical approach to this technique was to measure the scattered light for a range of different angles and different solution concentrations such as to produce a Zimm plot which would allow determination of both the molecular weight and the shape of the molecule in solution. In the early 1970s, the introduction of laser light scattering instruments allowed the optical cell to be reduced in size to be compatible with a chromatographic detector cell and to work at a low enough angle to avoid the need for extrapolation to zero angle. These Low-Angle Laser-Light Scattering (LALLS) instruments allowed the stand-alone measurement to be carried out far more efficiently but were immediately used for direct combination with SEC such that the 'absolute' measurement of the molecular weight distribution was practical for the first time.

More recently, other instruments have been introduced which measure the scattered light at a range of angles simultaneously; these are known as Multi-Angle Laser-Light Scattering (MALLS) detectors. Instruments have also been introduced which only monitor the light scattered at a right angle (RALLS).

In addition to providing information on the absolute molecular weight distribution, SEC-light scattering is used to obtain information on branching

(basically by comparing the absolute molecular weight with the apparent molecular weight for the linear polymer calibration). The response of the light scattering detector increases dramatically with molecular weight and SEC-light scattering systems are very good at examining any variation at the high molecular weight end of a distribution.

In SEC-light scattering, the solution concentration is an important parameter in the calculation and it is necessary to have accurate information of the differential refractive index for the polymer/solvent (this is a squared term in the calculation). This requirement for information on the differential refractive index is problematic for examination of copolymers.

SEC with Viscosity Measurement

As noted above, it has been empirically demonstrated that for many polymer types, a universal calibration is obtained if the log. product of molecular weight and intrinsic viscosity is used rather than simple log. molecular weight. This is utilized by combining the response of a viscosity detector and a concentration detector to give the universal calibration directly. The viscosity monitor measures the differential pressure as polymer solution travels through a capillary; detectors have been developed which use a single capillary, a pair of capillaries or four capillaries (arranged in a manner analogous to a Wheatstone bridge).

SEC-viscosity is not theoretically an absolute approach but should give the true molecular weight distribution, providing that the polymer of interest conforms to the Universal Calibration approach. As with SEC-light scattering, SEC-viscosity is valuable for obtaining information on branching. Again, the solution concentration is an important parameter in the calculation. The differential refractive index does not appear in the calculation but could produce inaccuracies in the assumed concentration and hence is also problematic for copolymers.

Commercial hardware and software is available for combining SEC-light scattering-viscosity within a single system.

Future Prospects

Although there have been suggestions that other techniques (e.g. matrix-assisted laser-desorption ionization – time-of-flight, MALDI-TOF, mass spectroscopy) might replace SEC, there seems little prospect of this in the near future.

There are new commercial integral SEC systems now available that should simplify some of the more difficult applications and make SEC combined techniques more routine. These developments should ensure that SEC is a main stream technique for the foreseeable future. There will also probably be more utilization of triple-detection (concentration, viscosity and light-scattering) for detailed characterization of specific polymer types.

Introduction

Surfactants are molecules that exist as monomers when they are at low concentrations in solution,

while above their critical micelle concentration (c.m.c.) they associate to form aggregates called micelles. Two zones of different polarity exist in the molecules of surfactants: one is hydrophobic in nature, formed from one or more hydrocarbon chains; the other can be polar or even ionic. According to the nature of this second zone, surfactants are classified into three main categories: ionic (anionic and cationic), nonionic and zwitterionic (amphoteric).

The combination of hydrophobic and hydrophilic properties confers some special characteristics on micellar systems in aqueous solution. This has made these systems applicable in different areas of analytical chemistry, highlighting the increasing interest in their use in separation methods. The ability of micellar systems to solubilize hydrophobic compounds in aqueous solutions, to improve different analytical methodologies, or to develop new analytical methods due to the possibility of increasing sensitivity or selectivity should be emphasized.

In 1980, Armstrong and Henry showed the possibility of employing solutions of surfactants at a concentration above their c.m.c. as mobile phases for high performance liquid chromatography (HPLC), giving rise to micellar liquid chromatography (MLC). This technique, in which nonpolar chemically bonded stationary phases are generally used, constitutes an interesting alternative to aqueous-organic mobile phases in HPLC since micellar mobile phases are low cost and have low toxicity as compared with aqueous-organic mobile phases.

The great variety of interactions that are possible in MLC separations, for example electrostatic, hydrophobic and esteric, and the modification of stationary phase by adsorption of monomeric surfactants, make these systems more complicated than conventional reversed-phase HPLC (RP-HPLC) with aqueous-organic mobile phases. Micelles are not static species, but they exist above the c.m.c. in equilibrium with surfactant monomers. In a chromatographic column, surfactant monomers can be adsorbed on the surface of the stationary phase. For most surfactants and stationary phases, the amount of surfactant adsorbed remains constant after equilibrium between mobile and stationary phase is reached. The adsorption of a surfactant on a silica-bonded stationary phase, such as C_1 , C_8 and C_{18} , can occur in two ways:

1. **Hydrophobic adsorption.** The alkyl hydrophobic chain of the surfactant is adsorbed and the ionic head is in contact with the polar solution, conferring on the stationary phase some ion-exchange properties when charged solutes are separated.
2. **Silanophilic adsorption.** The ionic head of the surfactant is adsorbed by the stationary phase, thus acquiring a more hydrophobic character.

Figure 1 shows the different equilibria existing in MLC. First, a solute can be partitioned between the aqueous mobile phase and the micellar mobile pseudophase, this equilibrium being controlled by a distribution coefficient P_{MW} . Second, this solute can be in equilibrium between the stationary phase and the micellar pseudophase, which is characterized by a distribution coefficient P_{SM} , and finally, a third

Figure 1 Distribution equilibria of a solute in micellar liquid chromatography. (Reproduced with permission from Marina ML and García MA (1997) *Journal of Chromatography A* 780: 103–116, copyright Elsevier Science Publishers B.V.)

equilibrium can be established for the solute distribution between stationary and aqueous mobile phases (P_{SW}).

Equations Describing Solute Retention in Micellar Liquid Chromatography

Table 1 groups some of the different models developed to describe solute retention in MLC. Some physicochemical models explain the variation of solute retention generally as a function of one or two experimental variables (micellar concentration, organic modifier concentration and pH). Empirical models, without a chemical sense, have also been developed to predict solute retention in MLC under different experimental conditions.

Purely Aqueous Micellar Systems

From equilibria taking place in MLC represented in Figure 1, equations have been developed relating chromatographic retention and concentration of micellized surfactant in solution.

Equation [1] (Table 1) relates the solute elution volume (V_e) in MLC with the micellized surfactant concentration in the mobile phase (C_M) (total surfactant concentration in solution minus c.m.c.). V_s , V_M and v are the stationary phase volume, the void volume of the column and the surfactant molar volume,

Table 1 Retention modelling in MLC

Model	Equations
Physico-chemical	$V_S/(V_e - V_M) = \{V(P_{MW} - 1)/P_{SW}\} C_M + 1/P_{SW}$ [1]
	$1/k = \{K_2/\phi[L_S]K_1\} C_M + 1/\phi[L_S]K_1$ [2]
	$k = (V_S/V_M) \cdot (P_{SW}/V C_M)$ [3]
	$k = \frac{k_0(1 + K_2[C_M]) + k_1(1 + K_4[C_M])K_{am}/[H^+]}{1 + K_2[C_M] + (1 + K_4[C_M])K_{am}/[H^+]}$ [4]
	$k = \frac{\phi K_1[L_S](1 + K_4[A_M])}{1 + (K_3 + K_4)[A_M] + K_2[C_M](1 + K_3[A_M]) + K_3K_4[A_M]^2}$ [5]
Empirical relationships	$\ln k = -S\phi + \ln k_0$ [6]
	$1/k = A\mu + B\phi + C\mu\phi + D$ [7]
	$1/k = A\mu + B\phi^2 + C\phi + D\mu\phi + E$ [8]

respectively. If solute retention is expressed as the retention factor (k), a similar equation is obtained (eqn [2]) relating $1/k$ with C_M through the solute-micelle association constant per monomer, K_2 . Here ϕ is the phase ratio (the ratio of the stationary phase volume to the volume of the mobile phase in the column, V_S/V_M), $[L_S]$ is the stationary phase concentration and K_1 is the binding constant for the solute between the bulk solvent and the stationary phase.

Equations [1] and [2] show that retention of a solute in MLC decreases when micelle concentration in the mobile phase increases. This is in contrast to reversed-phase ion-interaction (or ion-pairing) chromatography, where the surfactant concentration is below the c.m.c. (that is, no micelles exist), and the addition of an ionic surfactant increases retention for compounds that interact electrostatically with it.

For very hydrophobic compounds, a direct transfer retention mechanism from the micellar mobile phase to the modified stationary phase has been proposed. A limit theory has been developed for those compounds where the amount of the solute in the non-micellar aqueous mobile phase can be considered negligible. In this case, k is related to C_M through eqn [3] in Table 1.

For ionized solutes (weak acids, bases and zwitterionic solutes), some equations have also been developed relating k with C_M and pH. As an example, eqn [4] in Table 1 is the derived model for a weak acid. In this equation k_0 and k_1 are the limiting retention factors for the neutral and dissociated forms, respectively, K_4 is the association constant of the

ionized form of the solute with the micellar phase, and K_{am} is the acid dissociation equilibrium constant. The variation of k with pH at a constant micellized surfactant concentration is sigmoidal. Since a shift in the ionization constants can be obtained when the micellized surfactant concentration is modified, optimization of separation conditions must be attained considering both variables simultaneously.

Hybrid Micellar Systems

The addition of an organic modifier to a micellar solution can modify the characteristics of the micellar system (c.m.c. and the aggregation number). This can cause a variation of the solute-micelle interactions that, in turn, can change the chromatographic retention. On the one hand, a high concentration of alcohol can destroy the micellar structure, but on the other hand, the alcohol modifies the structure and composition of the stationary phase because it solvates the bonded hydrocarbon chain. Logically, the separation mechanism with the so-called hybrid mobile phases (micellar phases modified by alcohols) should be more similar to that for conventional aqueous-organic mobile phases than for purely aqueous micellar phases. However, if the integrity of the micelles remains, the addition of an alcohol to micellar mobile phases will not create an aqueous-organic system.

Both physicochemical and empirical models have been developed to describe the retention of solutes with hybrid mobile phases.

Physicochemical models Equation [5] (Table 1), which relates a solute retention factor with the micellized surfactant and alcohol concentrations, can be considered an extension of eqn [2]. This model considers the modification of stationary phase sites and micelle concentration due to the presence of an alcohol, that is, the alcohol can compete with the solute for interaction with the stationary phase and micelles. $[A_M]$ is the alcohol concentration in the mobile phase, and K_3 and K_4 are the association constants of the alcohol with the modified stationary phase and the micellar mobile phase, respectively. Based on the value of these constants and alcohol concentration, some simplified equations can be obtained. This model can predict a nonlinear, linear or quadratic variation of the retention factor with the alcohol concentration in the mobile phase (when micellized surfactant concentration is constant) and a linear variation of the inverse of retention factor with the micellized surfactant concentration (when alcohol concentration remains constant).

Empirical equations These models have no chemical background but are very valuable tools for predicting solute retention as a function of different variables. Among the different empirical equations reported in literature, models can be found relating solute retention to: (1) the organic modifier concentration, and (2) organic modifier and surfactant concentrations.

Empirical equations relating solute retention in MLC to organic modifier concentration Equation [6] (Table 1) is the simplest model relating the retention factor to the organic modifier concentration when surfactant concentration is constant. ϕ is the volume fraction of the organic modifier, S the eluent-strength parameter, and k_0 the retention factor in the absence of the organic modifier. Although this model can explain the decrease in solute retention observed in the presence of organic modifiers, deviations from linearity can be seen and some significant differences are obtained between the intercept and the experimental retention factor in the absence of an organic modifier. From an experimental viewpoint, its applicability is limited because the variation of the surfactant concentration is not considered.

Empirical equations relating solute retention in MLC to organic modifier and surfactant concentrations Equations have been obtained relating the logarithm of the retention factor to the volume fraction of the organic modifier (ϕ) and to the total surfactant concentration in the mobile phase (μ), but their applicability is limited. Other models have been proposed

relating the inverse of the retention factor with these two variables and these, from which eqns [7] and [8] (Table 1) are examples, have shown a more general application range.

An extension of the iterative regression optimization strategy to multiparameter optimizations for the separation of ionic compounds in MLC has also been reported. The parameters examined are surfactant concentration, alcohol concentration and pH. Fairly regular (linear, weakly curved) retention behaviour of compounds as a function of the parameters results in an efficient optimization using a relatively small number of initial experiments.

All the models presented above require a mathematical equation, derived from chemical considerations, or are empirical in nature, but there are other methods that, although also empirical, do not have such requirements; these are artificial neural networks (ANNs). Although ANNs have been known for years, they have been applied only recently to model retention in MLC with hybrid eluents. ANNs are a very promising alternative to classical statistical methods for retention modelling studies in MLC.

Efficiency

One of the main drawbacks of MLC techniques is the loss observed in the chromatographic efficiency as compared with that obtained in RPLC with aqueous-organic mobile phases. This efficiency loss is attributed to the increase in the resistance of solute mass transfer from the mobile phase to the stationary phase. However, the addition of small quantities of an organic modifier to the mobile phase and an increase in the working temperature have shown that efficiencies similar to those obtained in RPLC with aqueous-organic mobile phases may be attained. Other suggestions include working with low flow rates and low surfactant concentrations. Indeed, it has been shown that the use of a high surfactant concentration in the mobile phase may cause efficiency loss.

Surfactant adsorption on the stationary phase seems to have a great influence on the efficiency. The addition of a short or medium chain alcohol causes surfactant desorption out of the stationary phase and improves efficiency. This effect increases with increase in the modifier's concentration and hydrophobicity.

Elution Strength of Micellar Mobile Phases

A disadvantage of MLC techniques is that the eluent strength of micellar mobile phases is quite small.

Figure 2 Chromatograms corresponding to the separation of a mixture of 15 benzene and naphthalene derivatives. (A) 0.02 mol L⁻¹ SDS modified with 5% *n*-butanol. (B) 0.035 mol L⁻¹ SDS modified with 5% *n*-butanol. (C) 0.035 mol L⁻¹ SDS modified with 10% *n*-butanol. Key: 1, benzene; 2, benzylic alcohol; 3, benzamide; 4, toluene; 5, benzonitrile; 6, nitrobenzene; 7, phenol; 8, 2-phenylethanol; 9, chlorobenzene; 10, phenylacetone; 11, 3,5-dimethylphenol; 12, naphthalene. Column: Hypersil C₁₈ (10 cm × 4.0 mm i.d.). (Reproduced with permission from García MA, Vera S, Bombin M and Marina ML (1993) Optimization of the separation selectivity of a group of benzene and naphthalene derivatives in micellar high-performance liquid chromatography using a C₁₈ column and alcohols as modifiers in mobile phase. *Journal of Chromatography* 646: 297–305, copyright Elsevier Science Publishers B.V.)

Although the eluent strength of purely micellar eluents increases when the micelle concentration in the mobile phase increases, an increase of the micelle concentration in the mobile phase generally causes an efficiency loss. For these reasons, the addition of organic modifiers to micellar mobile phases is of great interest since it is possible to increase both eluent strength and efficiency. As an example, **Figure 2** shows the chromatograms corresponding to the separation of a mixture of 15 benzene and naphthalene derivatives when the following sodium dodecyl sulfate (SDS) mobile phases are used: 0.02 mol L⁻¹ SDS modified with 5% *n*-butanol (chromatogram A), 0.035 mol L⁻¹ SDS modified with 5% *n*-butanol (chromatogram B) and 0.035 mol L⁻¹ SDS modified with 10% *n*-butanol (chromatogram C). It can be observed that for the same alcohol percentage in the mobile phase, the elution strength increases with the surfactant concentration (Figures 2A and 2B), while for the same surfactant concentration in the mobile phase, elution strength increases with the alcohol percentage (Figures 2B and 2C).

The eluent strength of a micellar mobile phase modified by a short or medium chain alcohol such as methanol, propanol or butanol increases with the length of the alcohol chain as in conventional aqueous-organic systems.

Separation Selectivity

The rate of change in retention of different solutes varies with charge and hydrophobicity of the solute as well as with the length of alkyl chain, charge and concentration of micelles. This causes inversions of elution order that are the result of two competing equilibria: the solute-micelle association, characterized by K_2 , and the solute-stationary phase interaction, characterized by P_{sw} . The parameters K_2 and P_{sw} have a different effect on retention. When P_{sw} increases, retention also increases, but when K_2 increases, retention decreases. When the surfactant concentration in the mobile phase increases, the effect that K_2 has on retention also increases and reversals in elution order can be obtained if the difference in K_2 values for two solutes is large. Therefore, separation selectivity in MLC can be controlled by modifying surfactant nature and concentration. Furthermore, when organic modifiers are added to the mobile phase, the solvent strength parameter for a group of compounds does not have the same ranking for different alcohols owing to the different interaction of these modifiers with the micelles. For these reasons, MLC techniques are very interesting for chromatographic separation.

Although the conditions that optimize separation selectivity in MLC can vary with the nature of the solutes, several workers have shown an increase in separation selectivity for aromatic compounds in MLC with hybrid eluents when the micelle concentration in the mobile phase decreases. However, for a group of amino acids and peptides, an increase in micelle concentration can cause an increase or decrease in selectivity, or even an inversion of the peaks.

The effect of the organic modifier content in the mobile phase seems to be clearer. Generally, separation selectivity in MLC is improved in the presence of an organic modifier and increases with the volume fraction of the modifier in the mobile phase. This result is opposed to that observed in conventional RPLC with aqueous-organic mobile phases in which an increase of the organic modifier content causes a decrease of solute retention and selectivity. The selectivity enhancement observed in MLC when the solvent strength increases has been attributed to the competing partitioning equilibria in micellar systems and/or to the unique abilities of micelles to compartmentalize solutes and organic solvents. For some compounds, however, selectivity can decrease with the content of the alcohol in a micellar (SDS) mobile phase. In this case, for pairs of peaks where the selectivities are reduced by increasing alcohol concentration, a selectivity enhancement is observed with increasing micelle concentration and vice versa. Micelles and alcohols compete to interact with solutes affecting the role of one another in controlling retention and selectivity. The mutual effects of micelles and organic modifiers on each other also require a simultaneous optimization of these two parameters.

The retention mechanism of a solute in MLC can have implications for selectivity. If the retention of a solute in the chromatographic system takes place through a direct transfer mechanism, then the retention factor can be expressed by eqn [3] (Table 1). In this case, and if the surfactant concentration in the mobile phase is high, the selectivity coefficient (α) for a pair of solutes can be calculated from the ratio of their distribution coefficients between the stationary and micellar phases (P_{SM}):

$$\alpha = P_{SM1}/P_{SM2} \quad [9]$$

This equation is useful for two reasons. First, because knowledge about the retention mechanism of compounds in the chromatographic system can be enhanced. In fact, if the experimental selectivity coefficient for a pair of solutes is constant and coincides with the ratio of their respective distribution coeffi-

cients, P_{SM} , it can then be assumed that retention occurs through a direct transfer from the micellar phase to the stationary phase. Second, calculation of the selectivity coefficient from eqn [9] enables prediction of the separation selectivity of two compounds in the chromatographic system, provided the distribution coefficients (P_{SM}) of the solutes are known.

As an example, Figure 3 shows the variation of theoretical and experimental selectivity coefficients as a function of the micellized surfactant concentration in two mobile phases, SDS/5% *n*-propanol (Figures 3A, 3B and 3C) and hexadecyltrimethylammonium bromide (CTAB) modified by 5% *n*-butanol (Figures 3D, 3E and 3F) for three pairs of aromatic solutes. For pyrene/acenaphthene, both of which are highly hydrophobic, a direct transfer mechanism can be assumed for any surfactant concentration in these mobile phases. For pyrene/toluene a direct transfer mechanism can only be assumed for pyrene in all surfactant concentrations. For pyrene/benzamide, benzamide does not experience a direct transfer mechanism except at very high surfactant concentrations. Figure 3 shows that, when both solutes experience a direct transfer mechanism, the experimental and theoretical selectivity coefficients are very similar for all surfactant concentrations in solution, and it is therefore possible to predict the selectivity coefficient from the partition coefficients P_{SM} for the two solutes. When one of the two solutes does not experience a direct transfer mechanism, the theoretical and experimental selectivities are different. This difference decreases under conditions in which the direct transfer mechanism is favoured, i.e. by increasing the solute hydrophobicity, solute-micelle association constants, surfactant concentration in mobile phase and, for mobile phases modified by alcohols, by increasing the polarity of the alcohol. Consequently, the separation selectivity for a pair of solutes shows a tendency to match a limit value close to the ratio of stationary-micellar partition coefficients of two solutes. In this case, the separation selectivity cannot be experimentally modified through a change in the surfactant concentration in the mobile phase.

Applications

Determination of Solute-Micelle Association Constants and Distribution Coefficients

From eqn [1] in Table 1 it can be seen that a plot of the term $V_s/(V_e - V_m)$ versus C_M is linear and the term ' $\nu(P_{MW} - 1)$ ' can be obtained from the slope: intercept ratio. According to Berezin's treatment the term ' $\nu(P_{MW} - 1)$ ' is equal to the solute-micelle

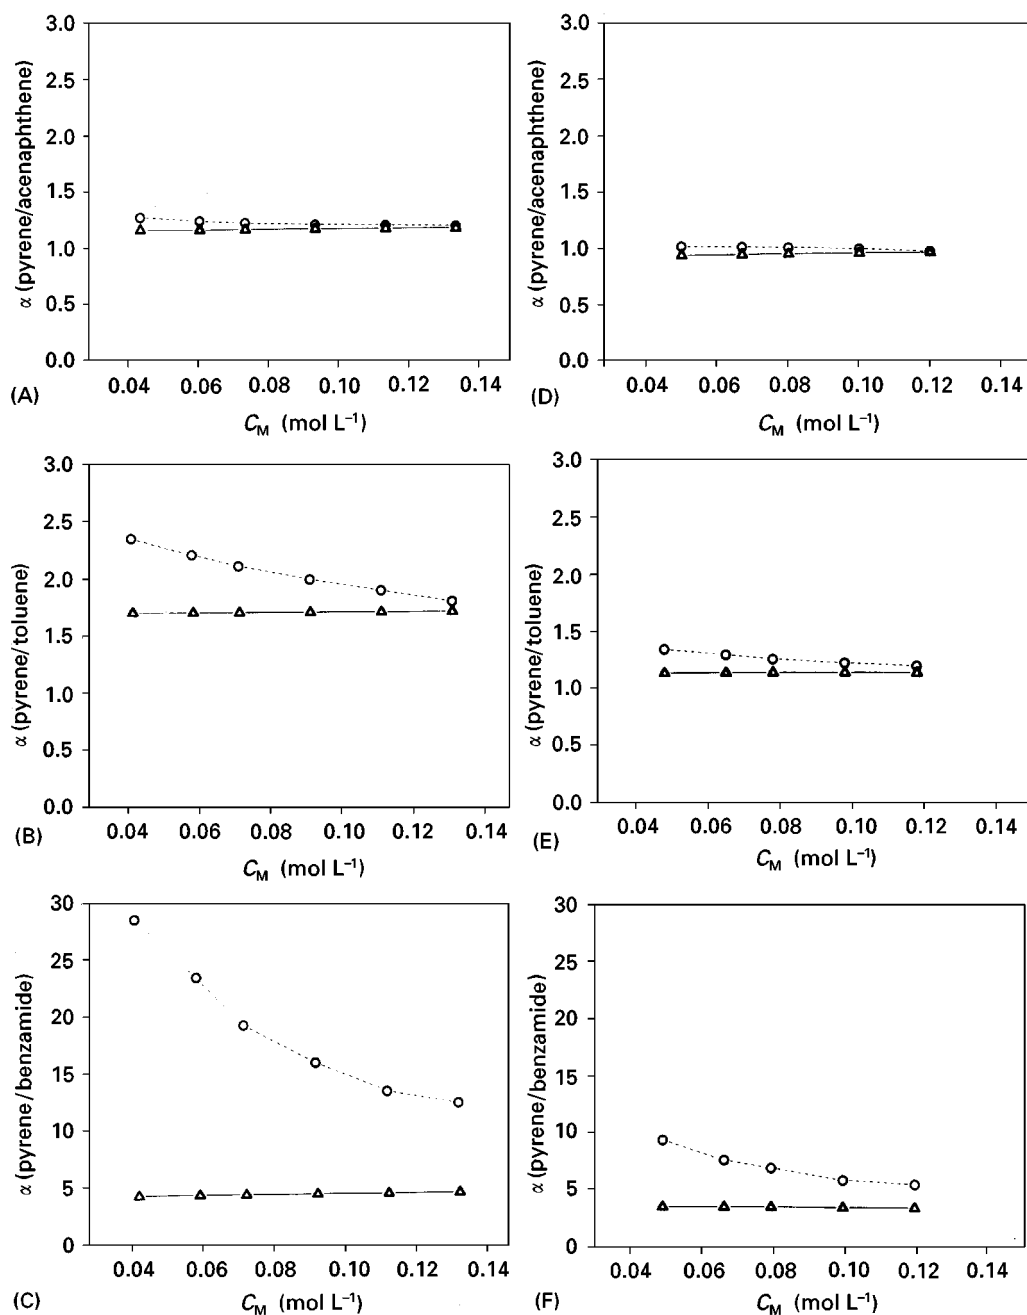

Figure 3 Variation of the experimental (—○—) and theoretical (—△—) selectivity coefficients (α) as a function of the micellized surfactant concentration for three pairs of solutes: pyrene/acenaphthene (A and D), pyrene/toluene (B and E) and pyrene/benzamide (C and F). Mobile phases: A–C, SDS/5% *n*-propanol; D–F, CTAB/5% *n*-butanol. Column: Spherisorb C_8 (15 cm \times 4.0 mm i.d.). (Reproduced with permission from García MA and Marina ML (1996) Influence of alcohol organic modifiers upon the association constants and retention mechanism for aromatic compounds in micellar liquid chromatography. *Journal of Liquid Chromatography and Related Technologies* 19: 1757–1776, copyright Marcel Dekker, Inc.)

association constant per monomer, K_2 , which is the parameter most used to evaluate solute–micelle interactions. Also, the partition coefficient of the solute between bulk water and micelle, P_{MW} , can be obtained if the surfactant molar volume, v , is known. The distribution coefficient, P_{SW} , is obtained directly

from the intercept and the distribution coefficient P_{SM} can be obtained from the ratio P_{SW}/P_{MW} .

In a similar way, the solute–micelle association constant per monomer, K_2 , can be obtained directly from eqn [2] in Table 1 as the slope/intercept ratio of a straight line obtained from a plot of $1/k$ versus C_M .

If the solute-micelle association constant per monomer obtained from eqns [1] or [2] is multiplied by the aggregation number of the micelle, the association constant per micelle is obtained. On the other hand, P_{MW} and K_2 values only depend on the solute and the micellar system employed but not on the stationary phase.

Equations [1] and [2] have frequently been employed with the aim of determining solute-micelle association constants in pure and modified micellar media. Furthermore, good agreement has been found between the values of the association constants obtained by MLC and other techniques.

Figure 4 provides an example of the good linearity obtained for the variation of the term $V_s/(V_e - V_m)$ as a function of C_M for a group of 12 polycyclic aromatic hydrocarbons when an SDS micellar mobile phase modified by 5% *n*-butanol is used.

For highly hydrophobic solutes, the retention of which is described by eqn [3] in Table 1, the variation of $1/k$ as a function of C_M should give a straight

line with an intercept equal to zero; the slope of the line should allow calculation of the distribution coefficient P_{SM} . In these cases, calculation of solute-micelle association constants is not possible and has no chemical meaning.

One of the main drawbacks that this method has is the intrinsic error derived from the determination of a magnitude from a quotient. Error obtained during the determination of K_2 increases with solute hydrophobicity since P_{SW} values for these compounds are elevated (intercept very small, see eqn [1]). With hybrid eluents, the value of P_{SW} decreases and the error in the determination of the solute-micelle association constants for very hydrophobic compounds also decreases (the intercept in eqn [1] increases).

Rapid Elution Gradients

Gradient elution techniques are the most versatile and popular techniques for solving the general elution problem in liquid chromatography. The advantages of gradient elution are enhanced peak resolution, faster analysis times, and better detectability. The major disadvantage is that the compositions of the stationary and mobile phases change during the course of the separation and column regeneration is needed before the next analysis. In order to perform gradient elution in MLC, the concentration of micelles and/or organic modifier may be increased during the course of the separation. In a micellar concentration gradient, re-equilibration time at the end of a gradient run is not necessary, and in an organic modifier gradient the re-equilibration time is very short.

Micellar gradients Rapid micellar elution gradients can be performed in MLC because re-equilibration time for the column is not necessary. This is because the amount of surfactant adsorbed on the stationary phase remains practically constant after reaching equilibrium when the concentration of surfactant in the mobile phase is above the c.m.c. Accordingly, micellar elution gradients are compatible with electrochemical detection. Figure 5 shows the separation of eight organic compounds using a micellar gradient and electrochemical detection.

Organic modifier gradients Organic solvent gradients in MLC require short re-equilibration times at the end of the gradient mainly due to the small range of organic modifier concentration used in MLC in order to maintain micelle integrity. In this case, the change in the concentration of organic modifier is not sufficient to change the concentration of adsorbed surfactant monomer in the stationary phase. In MLC,

organic modifier gradients are useful since although a limited range of organic modifier may be used, the solvent strength can be compensated with a concurrent micelle concentration gradient. **Figure 6** shows the separation of a mixture of amino acids and peptides in MLC under isocratic and gradient conditions.

Enhancement of Detection Sensitivity

Luminescence detection can be improved in MLC because many solutes show enhanced fluorescence and in some cases room temperature liquid phosphorescence when associated with micelles. The fluorescence intensity of certain compounds in micellar media can be drastically increased as a result of solubilization in the micelle. The location of a solute in the anisotropic medium of micelles, which have a large microenvironment viscosity and different polarity from the aqueous bulk solvent, would result in a decrease in the freedom of movement, shielding of the compounds from nonradiation deactivation, and/or an increase in quantum efficiency. This leads to intensified fluorescence signals and thus to better sensitivity and lower detection limits. Room temperature phosphorescence in solution is possible in the presence of ionic micelles and heavy atom counterions, which increase the population of the triplet excited state molecules and protect them from radiationless deactivation.

Furthermore, many metal–dye complexes show increased absorbance in the presence of micelles. This is

Figure 6 Separation of a seven-component test mixture. Mobile phase: 0.30 mol L^{-1} SDS, 0.02 mol L^{-1} phosphate buffer, pH 2.5 with propanol added. due to the capacity of the micelles to produce hyperchromic and bathochromic displacements. Generally, these displacements result in greater sensitivity. In UV/Vis spectrophotometry, the upward displacement of the λ_{\max} of the complex, together with the effect that micellar solutions also have on the λ_{\max} of the ligand, normally enable a more sensitive metal ion determination than that possible in nonmicellar media.

Figure 7 shows a comparison of the detected fluorescent peaks of identical concentrations of three aromatic solutes separated by HPLC. The enhanced fluorescence obtained with an SDS mobile phase with respect to that obtained with a methanol/water mobile phase is observed.

Direct Injection of Biological Fluids

From a bioanalytical viewpoint, a very useful application of MLC is the ability to inject biological fluids (serum, plasma and urine) directly into a chromatographic system with no protein precipitation, analyte extraction steps or pressure build-up problems. These advantages are extremely beneficial in areas such as therapeutic drug monitoring because the analyte extraction steps, traditionally necessary in chromatographic methods, are eliminated. In this way, analysis time is reduced and accuracy and precision are increased because the possible analyte co-precipitation with the protein is avoided.

Figure 7 Comparison of the detected fluorescent peaks of identical concentrations of pyrene (P), biphenyl (B) and naphthalene (N) separated by HPLC on a 30 cm \times 4.0 mm i.d. alkyl nitrile column. The broken line (---) shows the separation and enhanced fluorescence obtained with the 0.024 mol L⁻¹ SDS mobile phase. The solid line (—) shows an analogous separation done with a traditional 40 : 60 methanol/water mobile phase. In both separations 10 μ L of solution containing 1.3 \times 10⁻⁷ g (N), 7.0 \times 10⁻⁸ g (B) and 1.1 \times 10⁻⁸ g (P) were injected. Micellar systems such as SDS or polyoxyethylene lauryl ether (Brij-35) solubilize the serum proteins and cause their elution with the void volume. Furthermore, surfactant monomers compete with the analyte for protein-binding sites, thereby releasing it for complete quantitation.

Figure 8 shows the separation by MLC of a mixture containing diuretics (amiloride and spiro lactone), anabolic steroids (metandienone and clostebol) and a stimulant (phenylpropanolamine) added to a urine sample at concentrations of μ g mL⁻¹.

Hydrophobicity Estimation for Organic Compounds

Another interesting possibility of MLC techniques is their application to the quantitation of physico-chemical properties of biologically active compounds in QSAR (quantitative structure–activity

relationships) studies, especially for the prediction of hydrophobicity.

Hydrophobicity is commonly understood as a measure of the relative tendency of a solute to prefer a nonaqueous rather than an aqueous environment. Biological activity of many compounds, bioaccumulation of organic pollutants, and soil sorption of contaminants have all been correlated to the lipophilic character of the molecules concerned.

The quantitation of hydrophobicity has both diagnostic and predictive value in various disciplines such as drug design, toxicology and environmental monitoring.

Traditionally, the logarithm of the octanol–water partition coefficient ($\log P_{OW}$) of the nonionized form of a solute has been the most common parameter used to measure the hydrophobicity. The standard ‘shake-flask’ method for determining partition coefficients in liquid–liquid systems has several serious disadvantages. This fact, together with the use of a bulk solvent such as octanol as a model for complex systems such as biomembranes, has been occasionally criticized and has instigated the search for other indirect methods for evaluating hydrophobicity. Among these methods, chromatographic techniques such as reversed-phase TLC and HPLC can be highlighted. From 1977 several QSRR (quantitative structure–retention relationships) studies have appeared in the literature relating the biological activity of a solute and its retention in a chromatographic system. Good linear relationships between the logarithm of the retention factor ($\log k$) for series of organic compounds determined by RPLC and their $\log P_{OW}$ have been obtained.

The linear relationships obtained between $\log k$ determined by chromatographic techniques and $\log P_{OW}$ are based on the relationship existing between the logarithms of the distribution coefficients of a solute in two different systems, provided the interactions that the solute experiences in these systems are similar and the relationship can be expressed by an equation of the Collander type ($\log P_1 = a_1 \log P_2 + a_2$, where P_1 and P_2 are the distribution coefficients of the solute in the two different phases and a_1 and a_2 are constants).

The good linear correlations obtained between $\log k$ and $\log P_{OW}$ in RP-HPLC suggest that the Collander relationship is satisfied, that is, that the interactions of a solute in an aqueous–stationary phase system are similar to the interactions that the solute experiences in an aqueous–octanol one.

As micelles are considered to be simple chemical models for biomembranes, MLC has been investigated as an interesting possibility for evaluating the hydrophobicity of organic compounds. *n*-Octanol is

an isotropic solvent in which the molecular size and shape of the molecules are not important factors; however, micellar systems, like biomembranes, have amphiphilic properties and are anisotropic media so that the size and shape of molecules influence their penetration through them. The solubilization (or partitioning of solute into micelles) closely resembles that of lipid bilayers and both of these are different from the two-phase octanol–water system.

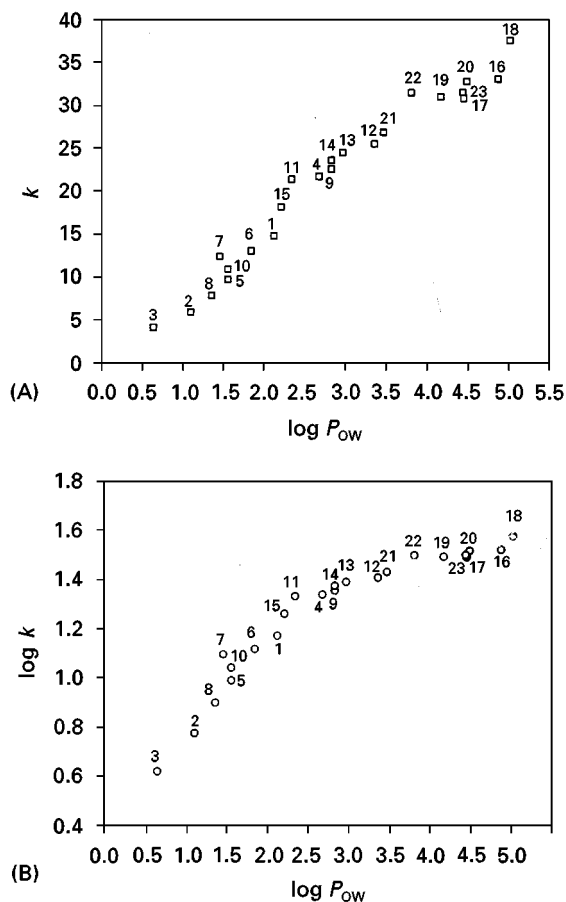

Figure 9 Variation of k (A) and $\log k$ (B) with $\log P_{OW}$ for a group of 23 benzene derivatives and polycyclic aromatic hydrocarbons in a 0.05 mol L⁻¹ CTAB/3% *n*-propanol mobile phase. Key: 1, benzene; 2, benzylic alcohol; 3, benzamide; 4, toluene; 5, benzonitrile; 6, nitrobenzene; 7, phenol; 8, 2-phenylethanol; 9, chlorobenzene; 10, phenylacetonitrile; 11, 3,5-dimethylphenol; 12, naphthalene; 13, 1-naphthol; 14, 2-naphthol; 15, 1-naphthylamine; 16, pyrene; 17, phenanthrene; 18, 2,3-benzofluorene; 19, fluorene; 20, fluoranthene; 21, acenaphthylene; 22, acenaphthene; and 23, anthracene. Column: Spherisorb C₈ (15 cm × 4.0 mm i.d.). (Reproduced with permission from Garcia MA and Marina ML (1994) Study of the k' or $\log k' - \log P_{OW}$ correlation for a group of benzene derivatives and polycyclic aromatic hydrocarbons in micellar liquid chromatography with a C₈ column. *Journal of Chromatography A* 687: 233–239, copyright Elsevier Science Publishers B.V.)

Contradictory results have been obtained concerning which of the two parameters (k or $\log k$) best correlates with $\log P_{OW}$ in MLC. Figure 9 shows the variation of k (Figure 9A) and $\log k$ (Figure 9B) with $\log P_{OW}$ for a micellar mobile phase, 0.05 mol L⁻¹ CTAB modified by 3% *n*-propanol, for a group of 23 benzene derivatives and polycyclic aromatic hydrocarbons. This figure shows that a good linear correlation between $\log k$ and $\log P_{OW}$ can be obtained for solutes with a low hydrophobicity, while, when high $\log P_{OW}$ values are attained, there exists a $\log P_{OW}$ value from which no further change for $\log k$ with $\log P_{OW}$ is obtained. This is due to the change in the retention mechanism of compounds from a three-equilibria mechanism to a direct-transfer mechanism from the micellar mobile phase to the stationary phase with increasing $\log P_{OW}$ for solutes. In fact, for highly hydrophobic compounds, which can become insoluble in water, the predominant equilibrium is the distribution between the micellar and stationary phases. Since these two phases are chemically similar, the distribution coefficient is close to unity and may become independent of solute hydrophobicity. In this way the variation of $\log k$ with $\log P_{OW}$ is represented by a curve.

Conclusion

MLC is a mode of HPLC in which solutions of surfactants at a concentration above their critical micellar concentration are employed as mobile phases. Three different equilibria exist for a solute in MLC. It can distribute between the aqueous mobile phase and the micellar mobile pseudophase, between the stationary phase and the micellar pseudophase, and between stationary and aqueous mobile phases. However, for highly hydrophobic compounds, a direct-transfer mechanism from the micellar to the stationary phase has been proposed. Solute retention is related to the concentration of micellized surfactant in the mobile phase through solute-micelle association constants or distribution coefficients that can be calculated as a direct application of MLC techniques.

The great number of interactions that are possible in MLC separations, such as electrostatic, hydrophobic and esteric, and the modification of the stationary phase by adsorption of monomeric surfactants, make these systems more complicated than conventional RP-HPLC. However, the fact that the amount of the surfactant adsorbed remains constant after equilibrium between mobile and stationary phases allows MLC techniques to achieve rapid micellar and organic modifier gradients.

The control of separation selectivity in MLC can be performed through a great number of parameters;

these include the nature and concentration of the surfactant in the mobile phase, the presence of additives as organic modifiers and salts, and the pH. The fact that the addition of an organic modifier to micellar mobile phases can increase selectivity and reduce analysis time has increased the use of hybrid micellar mobile phases, which also preclude the efficiency loss inherent to MLC as compared to conventional RP-HPLC.

Other applications that can be cited in MLC techniques are directly derived from the special characteristics of micellar solutions. The sensitivity of the detection can be enhanced and biological fluids can be directly injected into the chromatographic systems because of the solubilization of the protein by some surfactants. Finally, the fact that micelles can be considered as chemical models for biomembranes has enabled the application of MLC to hydrophobicity estimation of organic compounds.

Multidimensional Chromatography

Trace organic separations are often made difficult by the large number of substances present in various kind of samples, by the similarities among the analytes, and by the need to remove major components in the sample. The advantages of using hyphenated systems to tackle such problems have been demonstrated and sequential separation techniques are also well suited. A characteristic feature of these methods is the use of two or more columns for the separation.

Separation in two dimensions has a substantial history. While methods such as two-dimensional (2-D) electrophoresis and thin-layer chromatography are 2-D in space, coupled column techniques are 2-D in time. In *offline* techniques, the fractions of the first column are collected in vials and reinjected onto the second column later. Interest in these techniques has been revived by increased automation. In 1973 Huber *et al.* proposed a two-channel multicolumn system which allowed an imitation of 2-D chromatography with columns as they existed at that time. In *online* techniques, manual or automatic switching by a valve directs fractions between columns. Electrically controlled valves greatly facilitate the full automation of the chromatographic process, thus increasing the speed and the work capacity of the *high performance liquid chromatography* (HPLC) system. The terms column switching, coupled column chromatography and multidimensional chromatography are used interchangeably.

Column switching includes, in the widest sense, all techniques in which the flow path of the mobile phase is changed by valves, so the effluent from a primary column is passed to a secondary column for a defined period of time. An unlimited number of columns can theoretically be incorporated in a chromatographic network. However, in each successive step, the transferred fraction must be reconcentrated to reduce the dispersion of the analyte in the chromatographic system, and the dead volumes in the connections between columns and in any switching valves must be minimized to achieve maximum separation efficiency. The band spread problem can be approached by making a judicious choice of the order in which the dimensions are sequenced.

Multidimensional separations have been defined by Giddings as having only two criteria. The first is that

sample components must be displaced by two or more separation techniques based on different separating mechanisms. The second is that components separated by any single separation dimension must not be recombined in any further separation dimension. Most coupled-column approaches proposed only subject a portion of the sample to full 2-D or *n*-D analysis and are useful for the resolution of a single fused peak from the first dimension. They do not permit a comprehensive 2-D or *n*-D separation of the entire sample. The term linear heart-cut approach, used by Deans, describes the use of on-off valves in order to isolate an effluent segment which is then injected into a subsequent column. Comprehensive automated systems are useful for the greater resolution of multiple fused peaks from the first dimension column and resolved in the second-dimension orthogonal separation system.

Basic Theory and Configurations

Giddings' treatment of the peak capacity for a single mode leads to the expression:

$$\phi = 1 + \frac{N^{1/2}}{m} \ln(1 + k_n) \quad [1]$$

where $m = 4$ implies unit resolution (4σ separation), N is the plate number, and k_n is the retention factor for the last member of a series of peaks numbered from zero (nonretained) through to n (last peak out). A sequence of independent modes, each having a peak capacity ϕ_i , should exhibit a multiplicative separation effect with an overall result given by:

$$\phi = \phi_1 \times \phi_2 \times \dots \phi_n \quad [2]$$

With a conventional single-column approach the peak capacity increases with dwindling returns. To increase the peak capacity by a factor of 10, a 100-fold increase in column length would be necessary. In coupled chromatography however the effect is, theoretically, multiplicative and leads to an exponential increase with the number of columns within the configuration with different retention mechanisms.

Not all column types are compatible: typical examples of compatible systems with sufficiently different retention mechanisms are size exclusion and normal-phase chromatography, reversed-phase and ion

exchange chromatography, ion exchange and reversed-phase chromatography and polar bonded phase and normal-phase chromatography. The columns employed can have the same or different lengths: even a very short column, like a guard column, is used as the first column for some applications.

When one discrete zone is collected from the first-dimension column and reinjected into the second dimension, the resulting data are two individual one-dimension data sets. In linear coupled-column systems, the peak capacities of the individual columns can be summed, not multiplied. In so-called comprehensive automated system, the resulting data are a matrix, usually represented as a contour plot with each chromatographic separation along an axis.

The multidimensional resolution (R_s) for comprehensive multidimensional chromatography was suggested to be equal to the Euclidean norm of the resolution in each dimension. Schure *et al.* showed that this definition, under a certain set of assumptions, could be utilized to produce an experimentally simple method for 2-D resolution estimation:

$$R_s = \left[-\frac{1}{2} \ln \frac{1-P}{2} \right]^{1/2} \quad [3]$$

where P is the ratio of the difference between the amplitude at the valley and average peak maximum (f) and the average maximum peak (g) of the resulting one-dimensional chromatogram at the peak maxima in the contour plot, as shown in Figure 1 ($t_{1,x}$ and $t_{2,x}$ are the retention times of the peak maxima for peaks 1 and 2 in the x separation axis. The peak maxima in the y dimension are similarly denoted as $t_{1,y}$ and $t_{2,y}$).

A host of methods exist for coupling the various separation systems. In order to set up a switching network, the separation problem must be analysed and a valve configuration selected according to the solution. A review of commonly used switching networks is given by Ramsteiner (see Further Reading). These techniques only require minor modifications to existing equipment and, of equal importance, enable the sample preparation procedures to be completely automated.

For multidimensional chromatography a standard high pressure liquid chromatograph is used with the addition of one or more switching valves. These valves may be simple, manually operated six-, eight- or 10-port valves or may be automatically controlled. An eight-port valve with matching sample loops is typically used when the comprehensive mode of operation is utilized. When coupling two or more separation techniques online, not only has an interface to

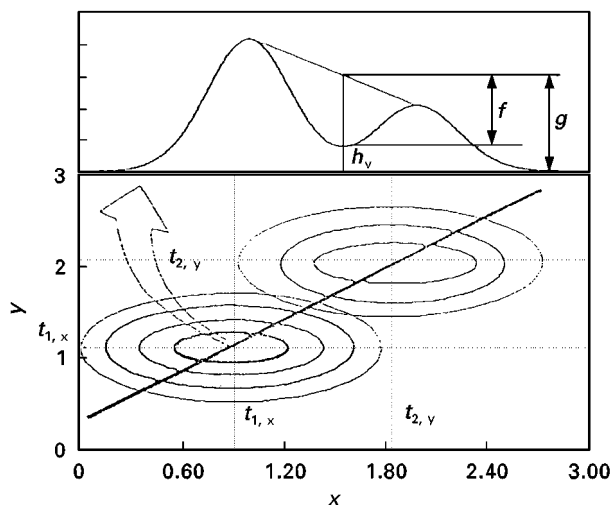

Figure 1 Schematic diagram of the two-dimensional resolution measurement using a 2-D contour (bottom) and the corresponding slice for resolution determination. be constructed but attention must be given to the effects of the injection volume and flow rates on the performance of the coupled system.

Scope of Multidimensional Liquid Chromatography

Multidimensional liquid chromatography (LC) is a powerful approach for demands such as improved analyte detectability and separating power, or the generally recognized need to increase sample throughput. In this sense, the main applications of multidimensional systems are analyte purification and enrichment, and improvement of the separation process (for instance, by increasing column length or by reducing the time of analysis), as will be illustrated in some detail below. In addition, because of their inherent flexibility, systems can be designed to achieve various objectives within a chromatographic network.

Sample clean-up

The main drawback of LC for the analysis of complex samples is the time-consuming and laborious nature of the sample pretreatment. Classic methods of clean-up often involve one or more liquid-liquid extractions, which have disadvantages such as the use of large volumes of organic solvents, the risk of contamination or the loss of analytes during evaporation and the final introduction of an aliquot of the (concentrated) extract into the LC column. Whereas

a chromatographic run often requires a few minutes, sample preparation time can be 1–2 h, and typically accounts for at least one-third of the error generated during the performance of the analytical method. Solid-phase extraction, although most commonly used as an offline technique, enables more rapid sample processing. Moreover, since a variety of stationary phases are available, better selectivity is generally achieved. However, the risk of contamination or loss of analytes, and the final introduction of an aliquot of the extract are ever-present drawbacks. In this respect, the employment of coupled columns is very well suited for the purification of complex samples before chromatography and today, coupling LC-LC is a well-established technique for sample clean-up, especially in the analysis of environmental, biomedical, pharmaceutical and food(stuff) samples.

The principle of multidimensional chromatography for sample clean-up is to transfer an effluent cut containing the analytes from a primary to a secondary column, whereas the remaining effluent containing unwanted compounds is vented to waste. In particular, the online coupling of a primary column, for the pre-separation of the analytes, with the analytical column via a switching valve greatly facilitates the analysis, as shown in Table 1. This table compares sample preparation steps typically involved in liquid–liquid extraction, and solid-phase extraction on to disposable cartridges, with those required by the multidimensional approach. As can be deduced from this table, a multidimensional approach drastically reduces, or even eliminates, manual sample preparation steps, and the entire analysis can be fully automated. In addition, the total time required for analysis is greatly shortened and the selectivity that can be reached is comparable to (and

sometimes better than) that obtained with traditional liquid–liquid or solid-phase extraction. Additional advantages over classical procedures are avoidance of an internal standard (and thus of sample dilution) and protection of the analytes during analysis (for example, light-sensitive or oxidation-sensitive compounds, as they can be kept away from light and air).

The success of the clean-up process mainly depends on the type of sample, the working conditions used in the first chromatographic dimension and the configuration of the system.

Type of sample In principle, any liquid sample can be processed by multidimensional LC (solid samples require prior dissolution and homogenization). However, the stability of the chromatographic system is often limited when processing complex matrices. For example, up to several hundred samples can be analysed with satisfactory stability when analysing water samples or biofluids with a low protein content (such as urine). However, regeneration or replacement of the primary column after a few injections may be required for fluids with a large amount of proteins (for instance, plasma or blood) due to the irreversible adsorption of the proteins to the stationary phase, or to the clogging of the pre-column. In most instances, this problem can be overcome simply by centrifugation or filtration of the sample. A prior treatment such as acidification, or the addition of an organic solvent or a selective displacer, aimed to increase the free concentration of analytes tightly bound to matrix constituents may also be required.

Primary column The effectiveness of clean-up mainly depends on the ability of the primary column to

retain selectively the compounds of interest. In general, small columns (often called pre-columns), typically $2\text{--}10 \times 1\text{--}4.6\text{ mm i.d.}$, are preferred. Small size reduces cost, allows fast sampling and prevents band broadening during the analyte transfer to the analytical column. Longer columns provide higher resolution, which might be required for some applications. On the other hand, particle sizes in the $10\text{--}40\text{ }\mu\text{m}$ range are used to prevent pre-column clogging.

The stationary phase must be chosen according to the type of sample and the characteristics of the compounds to be analysed. For example, common reversed-phase materials, which are used in most published procedures, allow the retention of a wide variety of compounds of low to medium polarity. This makes the multidimensional approach very useful in the biomedical field, since proteins, salts and other highly polar matrix constituents are flushed to waste in the first fraction of eluent, while retaining the compounds of interest. Next, the analytes are desorbed and transferred to the analytical column for complete resolution. Obviously, pre-columns with a stationary phase similar to that of the analytical column provide little extra selectivity, but flushing of the pre-column with the correct solvent gives the required selectivity for most applications. This is illustrated in **Figure 2**, which shows the elution time profile obtained for untreated urine ($50\text{ }\mu\text{L}$) in a $20 \times 2.1\text{ mm i.d.}$ pre-column packed with a C_{18} stationary phase. When using water as the mobile phase (washing solvent), the vast majority of matrix components are eliminated from the pre-column

Figure 2 Elution time profile obtained for untreated urine in a pre-column packed with C_{18} stationary phase.

within the first $1\text{--}1.5\text{ mL}$ of eluent. Therefore, satisfactory preseparation can be achieved by incorporating a flushing step, provided that the analytes are not eluted from the first column during the washing stage. As an example, **Figure 3** shows the chromatograms obtained for a urine sample on a C_{18} analytical column, after flushing the pre-column with 1 mL of water. This figure also shows the chromatogram obtained for the same sample when a C_{18} solid-phase extraction cartridge was used offline for sample clean-up. As can be seen from this figure,

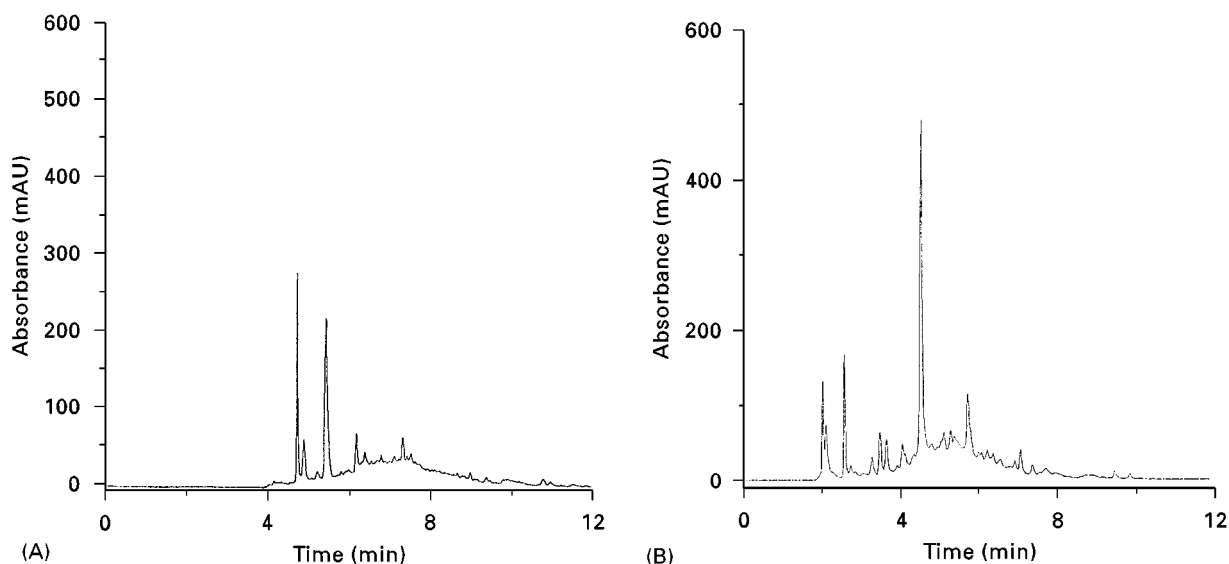

Figure 3 Typical chromatograms obtained from a urine sample by (A) online and (B) offline sample clean-up. Conditions: detection wavelength 230 nm ; analytical column, Hypersil ODS C_{18} ($5\text{ }\mu\text{m}$, $250 \times 4\text{ mm i.d.}$); mobile phase, acetonitrile- 0.05 mol L^{-1} phosphate buffer ($\text{pH } 3$).

the selectivity that can be reached is comparable to or even better than that obtained with solid-phase extraction cartridges. In some instances, selectivity can be improved simply by using a buffer or a specific modifier (an organic solvent or a surfactant) in the washing eluent.

Alternatively, a different chromatographic mode can be used to prepare the analytes. For example, gel permeation materials are effective for the elimination of high molecular mass matrix components before reversed-phase chromatography, which is particularly useful in the analysis of biofluids. A packing material specially designed for this field is the internal surface reversed-phase silica support (ISPR). ISPR materials confine the partitioning phase exclusively to the internal regions of the particles. Therefore, only interaction with small molecules is possible while the macromolecules are unretained since the external surface is nonadsorptive to them. The analysis of polar compounds requires different stationary phases. For example, ion exchangers or metal-loaded phases can be used for the selective retention of polar pesticides from environmental samples. Applications with pro-

tein-coated phases, immobilized antibodies or different copolymers have also been described for the analysis of different kinds of samples. The combination of two or more pre-columns with complementary separation properties can also be used for handling the clean-up of complex matrices.

Configuration The system design also determines the reliability of the system. In the simplest configuration, only a switching valve is required in addition to a basic chromatograph, as shown in **Figure 4**. It should be noted that, during the sampling and clean-up steps, the eluent in the analytical column is stagnant. Therefore, this configuration may lead to considerable baseline fluctuations depending on the elution conditions, which limits its applicability. However, excellent results are achieved when no buffers are used in the mobile phase. This is illustrated in **Figure 4**, which shows the chromatogram obtained for a urine sample spiked with the diuretic triamterene processed with the system shown in the figure. More powerful systems can be achieved at a reasonable cost by using an additional pumping system

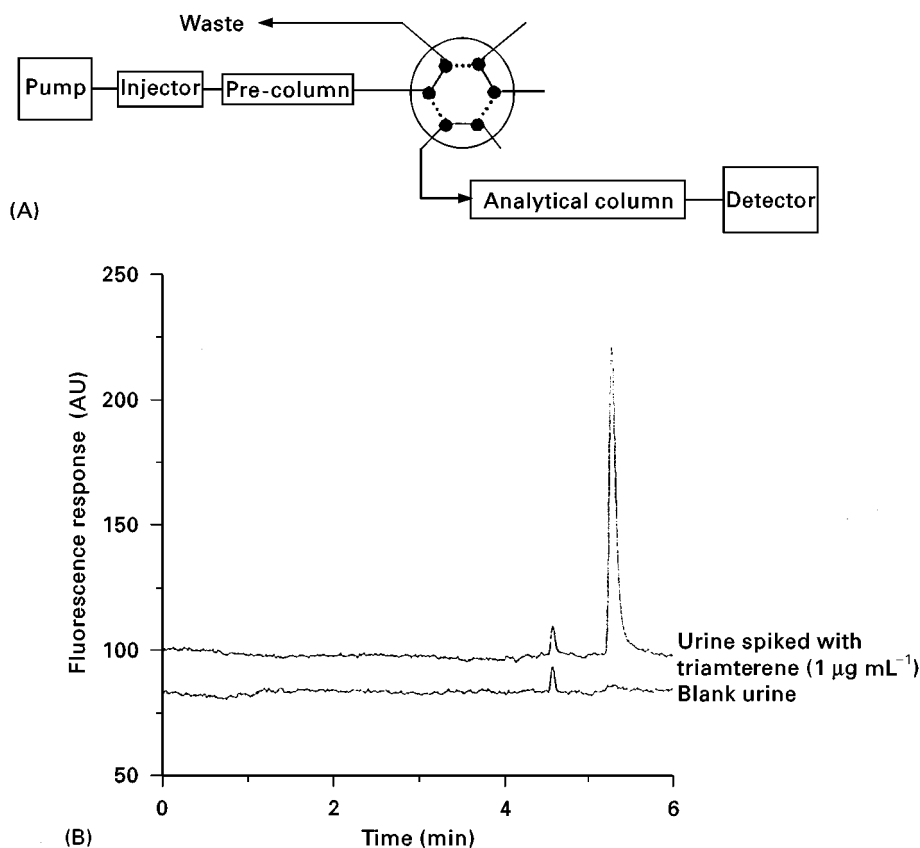

Figure 4 (A) Chromatographic system used for sample clean-up in straight-flush mode and (B) chromatogram obtained for clear and spiked urine sample with triamterene. Conditions: detection, excitation wavelength of 230 nm and emission wavelength of 430 nm; analytical column, LiChrospher 100 RP 18 (5 µm, 125 × 4 mm i.d.); mobile phase, acetonitrile–0.05 mol L⁻¹ phosphate buffer (pH 3). (A) Continuous lines, clean-up; dotted lines, transfer and separation.

Figure 5 Schematic representation of a conventional chromatographic system with back-flush configuration. Continuous lines, clean-up; dotted lines, transfer and separation.

(Figure 5). In such a way, the analytical column is equilibrated during the clean-up stage, and only the fraction of the eluent containing the compounds of interest is transferred to the analytical column.

Different transfer modes can be used. In forward-flush (also called straight-flush) configurations the flow direction in the pre-column is not changed during the transfer stage, which prevents solid particles retained at the head of the pre-column being sent to the second column. However, for samples containing compounds which are strongly retained in the pre-column, backflush configurations (in which the flow direction of the mobile phase through the pre-column is reversed for the transfer on to the second column) are preferable, because the desorption of the most retained components after every injection is easier.

Sample Enrichment

Sample enrichment is based on analyte retention in a pre-column when a large volume of sample is flushed through it. This column is then connected to the main column for separation of the analytes. An essential condition for this set-up is that the sampling solvent is a weak solvent with respect to the retention mechanism of the analytes in the first enrichment column. For example, since water is a noneluting solvent in reversed-phase LC, large volumes of aqueous samples can be passed through columns packed with hydrophobic chemically bonded phases for enrichment of rather apolar analytes. As for the sample clean-up, greater accuracy and precision can be expected in analyte enrichment by multidimensional LC compared with classical enrichment procedures, which are more time-consuming and prone to errors.

According to the basic principles indicated in the above section, the optimization of the chromatographic conditions should include careful selection of the pre-column (packing and dimensions) and system design, in order to achieve maximum analyte enrichment and minimum peak-broadening. The ultimate enrichment factor is determined by the breakthrough volume of the solute in the pre-column. For most applications, rather small columns, similar to those used in sample clean-up, provide successful results.

The enrichment of apolar compounds can be performed on C_{18} -bonded silica phases, while carbon-based materials or styrene-divinylbenzene provides sufficient resolution for the enrichment of relatively polar compounds (in environmental analysis, for instance). Maximum analyte detectability is reached by using a backflush configuration, which minimizes band broadening. Under optimized conditions, enrichment factors up to several thousand can be achieved.

Unfortunately, sample enrichment also concentrates components other than the analytes, thus limiting the degree of concentration possible. In this sense, the incorporation of washing stage after sample loading may improve the selectivity of the analysis. In such a case, an additional pump is required to deliver the washing solvent. In fact, many systems are designed to effect analyte enrichment and purification simultaneously.

Apart from the good compatibility of the sample with mobile phases used in reversed-phase LC, multidimensional chromatography is especially successful in the biomedical field, because sufficient sensitivity (high to low ng mL^{-1} level) can usually be reached with the direct injection of 0.1–0.5 mL of sample. However, trace analysis in water samples requires much higher sample volumes (50–100 mL). The employment of an LC pump for sampling allows such volumes to be loaded on to the pre-column. Published results demonstrate that detection limits of a few ng L^{-1} can be reached.

Enrichment via a pre-column can also be used to circumvent analyte dilution introduced by a different purification technique, for example, dialysis. Dilution, which is a serious problem when using online dialysis to remove macroconstituents from the sample matrix, can be overcome by refocusing the analytes in a pre-column before the chromatographic separation.

Improvement of the Separation Process

Multidimensional systems can be used to solve many problems encountered in the analysis of complex samples. Of particular interest are those systems designed to enhance the selectivity and to reduce the time of analysis.

The improvement in resolution is probably the most important application of multidimensional LC systems in the present context. The coupling of two or more chromatographic modes with complementary retention mechanisms considerably increases the resolution, provided that the separation modes are compatible. The great differences which are attainable due to the wide variety of separation modes available make multidimensional LC a very powerful tool for the resolution of complex mixtures and much more information can be obtained from a single run, especially if a comprehensive approach is used. A typical example is the analysis of proteins for peptide mapping. Reversed-phase LC coupled to mass spectrometry is generally used for peptide mapping, but the analysis of large proteins is often difficult due to the large number of fragments obtained from the enzymatic digestion of the protein. While mass spectrometry detection is useful to identify the presence of overlapping peaks, data interpretation becomes difficult if a large number of peptides co-elute. Difficulties also arise if the masses of the co-eluting peaks are similar and if the ^{13}C , ^{15}N or ^{18}O peaks overlap. A heart-cutting system combining size exclusion chromatography (SEC) and reversed-phase chromatography greatly facilitates the analysis. Two or more peptides co-eluting in the first SEC column could be transferred and separated in the reversed-phase column, because of the unlikely possibility that they would have the same molecular weight as well as the same hydrophobicity. In this approach, only the fractions containing co-eluting peaks are sampled into the reversed-phase column. A comprehensive configuration, however, offers substantially higher resolution, as fractions of the entire effluent from the SEC column are continuously sampled into the reversed-phase column. As a result, the peak capacity of the system is significantly increased, and exhaustive information from each sample can be obtained (three-dimensional data set). The addition of mass spectrometry allows the molecular weight information to identify accurately the chromatographic peaks. This kind of system has been successfully used for the characterization of proteins such as ovoalbumin and serum albumin in a reasonable time. As an example, Figure 6 shows a typical 2-D chromatogram of a protein sample.

Other interesting applications of two-dimensional systems with part or all of the sample passing into the second dimension deal with the separation of polymers, polymer blends, copolymers or large molecules. The combination of two columns operating under size exclusion and (partition) reversed-phase modes provides complementary information on molecular weight distribution, chemical structure and architec-

Figure 6 2-D chromatogram of protein sample. Automated instrumentation for comprehensive two-dimensional high-performance liquid chromatography of proteins. *Analytical Chemistry* 62: 161–167. Copyright 1990 American Chemical Society.)

ture, thus making possible the complete characterization of complex polymers with a single run. Another example is the separation of groups of compounds in oil samples. The coupling of size exclusion and normal-phase modes enables the separation of oil fractions, and the subsequent resolution of the analytes according to their polarity (if required, the system can be interfaced to a gas chromatograph, for further resolution according to volatility).

An area of special interest is the resolution of enantiomers. Although different combinations have been described, in the most commonly used configuration the first column (achiral) effects a separation of the compounds of interest, whereas only the fraction of the eluent containing the optical isomers is transferred to the second chiral column for enantio-resolution. This simplifies analysis, particularly in the biomedical field, because several matrix compounds can lead to pairs of peaks, thus making the resolution of the compounds of interest difficult. In addition, the

chiral column is better protected. An example of the kind of problems encountered in chiral analysis is the inability of many chiral stationary phases to separate parent drugs from metabolites. This is illustrated in **Figure 7**, which shows the chromatograms obtained for the calcium channel-blocking agent verapamil and its major metabolite norverapamil on an AGP chiral column. This column allows the enantioresolution of both compounds but overlap between *S*-verapamil and *R*-norverapamil is observed. The problem can be overcome by using an achiral–chiral system, where verapamil and norverapamil are initially separated from each other on the achiral (reversed-phase) column. The eluent fractions containing verapamil and norverapamil are then selectively transferred to the chiral AGP column for further separation of the enantiomers. A multidimensional approach can also be used to enhance the selectivity by effecting peak compression on an achiral column, after enantioresolution in a primary chiral column. This approach appears as an elegant alternative in

chiral analysis of drugs in biofluids or in multiresidue pesticide analysis.

Another area of application is the analysis of derivatized analytes. In this case, pre-separation or trapping in the first column allows a large amount of unreacted reagent or secondary products to be excluded for the second (analytical) column (**Figure 8**). Solid-phase reagents prepared by immobilizing detection-sensitive reagents on solid supports such as organic polymers can be used as column packings and integrated into the liquid chromatography system in order to form derivatives online. This methodology has been successfully applied to the derivatization of a variety of drugs. During the last 5 years, our research group has been studying the possibility of carrying out derivatizations with conventional octadecylsilica stationary phases. A possible online set-up for this purpose is shown in **Figure 4** or **5**. The system uses a 20×4.6 mm i.d. pre-column packed with an unmodified octadecylsilica stationary phase. This column is used to purify the sample and

Figure 8 Configuration used for online sample clean-up and derivatization. Continuous lines, derivatization; dotted lines, transfer and separation.

Figure 9 Chromatogram of an aqueous mixture of the amphetamines ($5 \mu\text{g mL}^{-1}$) derivatized online by using the configuration shown in Figure 5. Conditions: derivatization reagent, 9-fluorenylmethyl chloroformate; detection, excitation wavelength 264 nm and emission wavelength 313 nm; analytical column, LiChrospher 100 RP 18 ($5 \mu\text{m}$, $125 \times 4 \text{ mm i.d.}$); mobile phase, acetonitrile–water.

concentrate the analytes; the trapped analytes are derivatized by injection of the derivatization reagent into the pre-column. Finally, the derivatives are transferred to the analytical column by means of a switching arrangement. Some applications based on this methodology have been described for the determination of amphetamine and related compounds in urine, by using reagents such as 1,2-naphthoquinone 4-sulfonate, 9-fluorenylmethyl chloroformate and *o*-phthaldialdehyde. **Figure 9** is an example of the chromatograms obtained by this methodology.

Multidimensional systems can also be used to minimize the separation time of mixtures containing compounds of considerably different retention factors. In a column of high selectivity and under optimized conditions, compounds eluting at the start of the chromatogram can be generally well resolved, but later eluting compounds with long retention times may be difficult to detect. Conversely, if the column has low selectivity, the separation time will be shorter, but early eluting components will be poorly resolved. The coupling of two columns is well suited for such kinds of problems. The first column (short or low selectivity) is used to resolve the late eluting

components in a short time. These compounds are sent directly to the detector, whereas the poorly retained components are transferred to the second column (longer or more selective) for complete resolution. The overall effect is a considerable reduction of the time of analysis. This approach is a good alternative to gradient elution in those cases where a large number of plates is required, where a large number of samples will be analysed (as full automation is possible), or where detectors not compatible with gradient elution will be used.

An interesting form of this alternative is the so-called box car chromatography. The box car configuration involves partial separation of the compounds of interest in the first column, and subsequent transfer to a second column, where they are injected with the maximum frequency permitted by the resolution of the column. In this way, the separation power of the second column is fully utilized, and this considerably increases sample throughput. An example of the box car technique is the analysis of primidone and phenobarbitone in plasma. When utilizing a box car configuration, up to 40 samples per hour can be analysed, and this illustrates the potential of this technique.

Future Developments

Looking to the future, evolutionary development can be expected because the separating power of multi-dimension liquid chromatography is greatly increased over single-dimension liquid chromatography. The simultaneous improvements on both the software and the chromatographic apparatus will lead to a system capable of automatically developing analytical methods for a wide range of analytes in many different matrices. Other desirable aspects are a reasonably short analysis time and flexible operating conditions.

The thrust of multidimensional research will most probably be to improve the combination of separation methods, including coupling to alternative separation techniques.

Introduction

In many fields of chemistry, biology, pharmacy and medicine, progress is often limited by the ability to resolve complex analytical problems. To this end

analytical techniques have been developed in recent decades dealing with an integrated approach to the separation of mixtures together with structural elucidation of unknown compounds. High performance liquid chromatography (HPLC), gel permeation chromatography (GPC) and supercritical fluid chromatography (SFC), as well as the capillary separation techniques capillary HPLC (CHPLC), capillary electrophoresis (CE) and capillary electrochromatography (CEC) are the most powerful techniques

within the group of chromatographic separation methods. Nuclear magnetic resonance (NMR) spectroscopy, in particular, is useful because of its powerful stereochemical information content but it has the disadvantage of lower sensitivity in comparison to other methods, e.g. mass spectrometry (MS).

The combination of chromatographic separation techniques with NMR spectroscopy is one of the most powerful and time-saving methods for the separation and structural elucidation of unknown compounds and mixtures. Especially for the structure elucidation of light- and oxygen-sensitive substances, for example, hop bitter acids and carotenoid stereoisomers, online liquid chromatography (LC)-NMR has important advantages. Here, structure elucidation with LC-MS is not possible, because the carotenoid isomers exhibit the same fragmentation pattern. Using a classical method with offline separation, enrichment and transfer to a NMR sample tube, the isolated substances would be isomerized. A closed-loop LC-NMR flow-through system solves this problem. Online LC-NMR also allows the continuous registration of time changes as they appear in the chromatographic run. Unequivocal structural assignment of unknown chromatographic peaks is possible by two-dimensional stopped-flow LC-NMR experiments.

NMR Flow Cell Design

Figure 1 shows the design of NMR cells employed for various coupling techniques. For online HPLC-NMR and GPC-NMR coupling, a vertically oriented flow cell with a directly fixed double-saddle Helmholtz coil

is used (Figure 1A). The whole arrangement is centred in the glass dewar of a conventional probe body in which a thermocouple is inserted, allowing temperature-dependent measurements to be made. The internal diameter of the glass tube is 2, 3 or 4 mm, resulting in detection volumes of 60, 120 and 180 μL . The glass walls of the flow cell are parallel within the length of the proton detection coil, and taper at both ends to fit polytetrafluoroethylene (PTFE) tubing (i.d. 0.25 mm). PTFE and glass tubing are connected by shrink-fit tubing. Inverse continuous-flow probes contain an additional coaxial coil (tuned to the ^{13}C resonance frequency) surrounding the ^1H detection coil for heteronuclear $^1\text{H}/^{13}\text{C}$ shift-correlated experiments. This design leads to optimal NMR resolution values with a typical line width of chloroform at the height of the ^{13}C satellites of 9–12 Hz, allowing the determination of coupling constants of 1 Hz in continuous-flow NMR spectra. The disadvantage of this design is the high detection volume, leading to a degraded chromatographic resolution. For analytical HPLC columns (250 \times 4.6 mm i.d.) the plate height is increased for solutes with capacity factors less than 2.5 at detection volumes higher than 48 μL .

The probe design employed for SFC-NMR coupling is shown in Figure 1B. The inner glass tube of the original LC-NMR probe is substituted with a sapphire tube (o.d. 5 mm, i.d. 3 mm, detection volume 120 μL) and the polyetheretherketone (PEEK) capillaries used in the LC-NMR probe are replaced by Titan tubings. A double-tuned proton deuterium coil is directly fixed to the sapphire flow cell. The whole arrangement is centred in the glass dewar of

Figure 1 Design of NMR flow cell for: (A) HPLC-NMR and GPC-NMR experiments; (B) SFC-NMR experiments; (C) capillary NMR experiments.

a conventional probe body, in which a thermocouple is inserted, allowing temperature-controlled experiments.

Figure 1C shows the schematic diagram of the capillary NMR detection probe. Here a fused silica capillary is directly inserted within the NMR radio-frequency coil of a 2.0 mm microprobe. Within the area of the NMR detection coil the polyimide coating of the capillary is removed; either capillaries with an i.d. of 180 μm or bubble cell types with an increased i.d. of 220 μm are used.

Experimental Set-up

For online LC-NMR, GPC-NMR and SFC-NMR experiments, the chromatographic separation system consists of either HPLC or SFC pumps together with an injection valve, a separation column (250 \times 4.6 mm i.d.) and an ultraviolet (UV) or refractive index (RI) detector. The system is located at a distance of 2.0 m from an unshielded cryomagnet (Figure 2). With shielded cryomagnets, the chromatographic separation system can be located at a distance of about 30 cm. The outlet of the UV (RI) detector is connected by stainless steel capillary tubing (0.25 mm i.d.) to a switching valve. The valve is used to trap the desired peak in the NMR flow cell for stopped-flow experiments. For online experiments with continuous registration of NMR spectra in distinct time intervals (1–8 s), the switching valve is

open for a continuous flow through the probe to waste. Instead of the switching valve, a Bruker peak sample unit (BPSU) can be used. This technique is advisable when long NMR times are expected. Desired peaks from a separation can be stored in small capillary loops with the help of the peak sample unit. After complete separation, every single peak can be transferred into the probe and the desired stopped-flow experiment can be conducted.

In SFC-NMR experiments the outlet of the high pressure SFC probe is connected to a back-pressure regulator to guarantee supercritical conditions in the detection cell.

A feasible experimental set-up for online capillary LC-NMR coupling is outlined in Figure 3. The separation device for either pressure or electroosmotic flow-driven separations is located at a distance of 2 m from the cryomagnet. Separation is performed on a packed fused silica capillary which is directly fixed in a microprobe. For capillary HPLC separations a T-piece in conjunction with a restriction column is used for flow rate adjustment of the eluent. The HPLC pump, the injection device and the packed separation capillary are connected by fused silica capillaries.

LC-NMR Coupling

The coupling of LC-NMR requires the adjustment of both analytical systems. The flow of the mobile

Figure 3 Experimental arrangement for coupling a capillary separation technique with NMR spectroscopy.

phase leads to a restricted exposure period τ for the nuclei in the flow cell. The time τ is defined as the proportion of the detection volume to the flow rate. This is the reason for a shorter transverse relaxation time T_2 , which includes larger NMR signals. On the other hand the equilibrium state will be reached in a shorter time due to the permanent-flow nonexcited nuclei than only through the longitudinal relaxation time T_1 . This allows a quicker repeat time rate for exposure of a spectrum and therefore greater sensitivity.

LC-NMR spectroscopy is a relatively insensitive method requiring sufficient sample concentration in the NMR flow cell. However, the separation column should not be overloaded, because then separation may be impossible. Most HPLC separations are performed with reversed-phase materials using binary solvent mixtures such as acetonitrile–water, acetone–water or methanol–water as mobile phases. The choice of the mobile phase should be suited to the NMR spectroscopy. An obvious advantage is to obtain a small number of solvent signals in the NMR spectrum, because the solvent signals may obscure the sample spectra. Generally, the chromatographic conditions in HPLC-NMR experiments are the same as in conventional chromatography, but water is replaced by deuterated water. The use of deuterated

organic solvents is generally too expensive. For proper adjustment of the receiver gain of the NMR instrument, the solvent signals should be reduced to the height of the sample by applying a solvent suppression technique. Efficient solvent suppression can be performed, for example, by applying a NOESY-type presaturation scheme. With residence times in the order of 5 s and acquisition times of about 1 s, sufficient presaturation time is left even in the continuous-flow mode. Modern techniques like WET or WATERGATE sequences are based on a selective dephasing of the solvent signals using a magnetic field gradient.

Another problem is solvent purity. Most HPLC solvents have small amounts of impurities, often stabilizer additives. These additives have no UV activity and do not affect the chromatographic results, but will be detected in the NMR spectrum.

There exist in principle two general methods for carrying out LC-NMR: continuous-flow and stopped-flow experiments.

Continuous-flow Experiments

With this mode of operation the output of the chromatographic separation is recorded at the same time as the ^1H NMR spectra. In most cases the flow

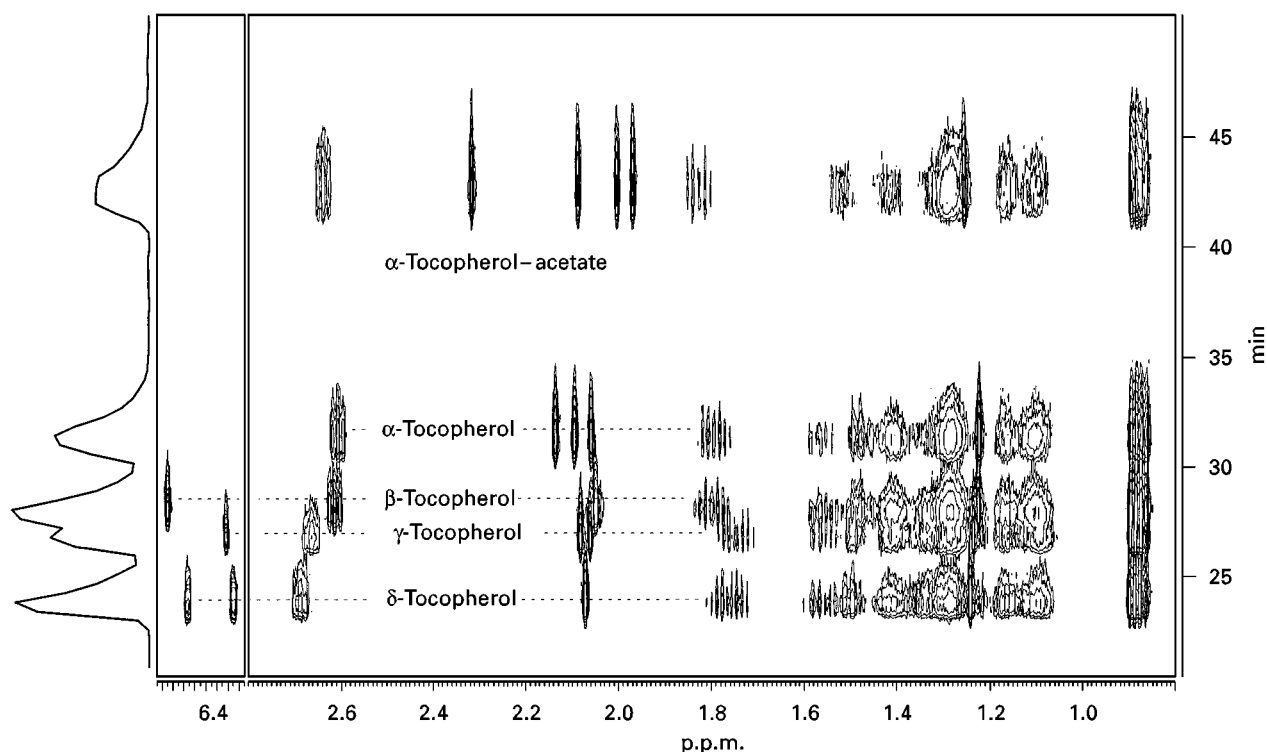

Figure 4 Contour plot (600 MHz) of the separation of tocopherol isomers.

rate of the mobile phase is decreased to yield an NMR scan accumulation of one chromatographic peak. The acquisition of online continuous-flow NMR spectra results in a two-dimensional contour plot of ^1H NMR signals of the separated compounds (x axis = ^1H chemical shift) versus retention time (y axis). **Figure 4** shows the contour plot of the separation of tocopherol isomers on a C_{30} stationary phase in methanol together with 2% CD_3OD . A time interval of 1 s was applied to presaturate the methyl group signal of the solvent. A total of 128 experiments with a time resolution of 27.3 were recorded at a flow rate of 0.3 mL min^{-1} . The chromatogram along the y axis was reconstructed by co-addition of all proton resonances between 0.8 and 1.9 p.p.m. The resolution of this ^1H NMR chromatogram suffers from the small number of 128 data points, but the separation of all five tocopherol isomers is readily apparent.

The structure of the separated compounds can easily be assigned by the methyl group ^1H NMR signals between 2.0 and 2.2 p.p.m. and by the aromatic resonances between 6.4 and 6.5 p.p.m. (**Figure 5**). For instance, the continuous-flow ^1H NMR spectrum of δ -tocopherol shows one signal for the methyl group at C_8 and two aromatic resonances with a small splitting due to the meta coupling between H_5 and H_7 . Thus, unequivocal structural assignment of all different isomers is possible by considering chemical shifts, coupling constants and integration ratios.

Stopped-flow Experiments

In continuous-flow experiments only a short time is available for accumulation of the ^1H NMR spectrum. Thus, this spectroscopic technique can only be used for high concentrations of the sample, since otherwise the signal to noise ratio is too low. The sample is transferred through the flow cell analogous to the continuous-flow experiment, but in the stopped-flow mode the valves of the sample unit switch and the chromatographic run is stopped as soon as the maximum of the peak reaches the flow cell (indicated by UV detector). At this point conventional NMR experiments can be performed and, therefore, the NMR experimental time can be adjusted to the sample concentration. Another advantage of the stopped-flow experiment is the possibility of multidimensional NMR spectra.

In **Figure 6** a correlation spectroscopy (COSY) stopped-flow spectrum of the olefinic protons of the carotenoid all-*trans* zeaxanthin is shown, recorded on a Bruker AMX 400 spectrometer. The number of experiments in F1 dimension was 216, the number of accumulated transients was 256.

Due to the centrosymmetric molecule, the corresponding protons are identical. By means of the cross-peaks in the coupling system, the structure can be elucidated. Proton H_{11} couples with two other protons, H_{10} and H_{12} , while proton H_{15} couples with

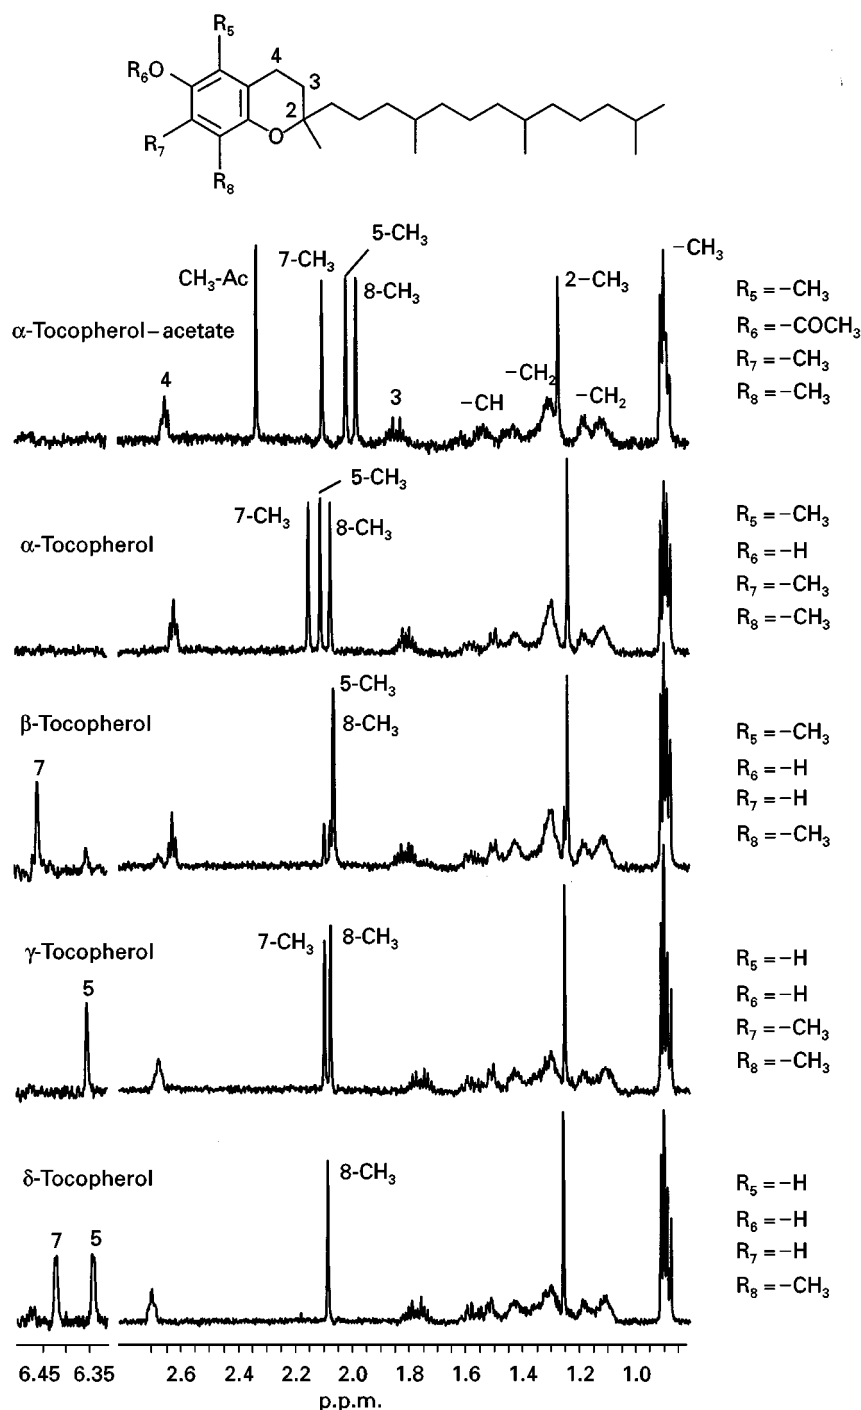

Figure 5 Continuous-flow 1H NMR spectra (600 MHz) of tocopherol isomers.

proton H_{14} . The cross-peak at 6.1 p.p.m. can be assigned to the proton H_7 and H_8 .

Figure 7 shows a stack plot of various zeaxanthin stereoisomers. Due to the *cis*-arrangements, the centrosymmetry of the molecule is repeated. Therefore, different resonance frequencies result for the shielded and unshielded protons. In Figure 7 the 1H NMR

spectra of all-*trans*, 13-*cis* and 9-*cis* zeaxanthin are depicted.

The assignment of *cis/trans* is adapted from the Karplus equation in general, with the difference that the coupling constants are available. In most cases the difference in the chemical shift values in systems with conjugated olefinic protons is more informative. They

Figure 6 COSY stopped-flow spectrum (400 MHz) of all-*trans* zeaxanthin.

can amount up to 0.6 p.p.m. Looking at the protons of the *cis*-bonding, the outer protons experience a shift to higher field, while the inner protons shift to lower field. As shown in Figure 7, the protons H_{12} and H'_{15} in 13-*cis* zeaxanthin shift to lower field and proton H_{14} to higher field. The protons H_{10} and H'_{15} also show a small influence. The other protons have the same chemical shift values as the all-*trans* zeaxanthin and the *cis*-bonding has no further influence. Analogous effects could be explained for the 9-*cis* zeaxanthin. Here the *cis*-bonding has no effect on the shielded protons and only the unshielded ones are affected.

SPE-LC-NMR Coupling

In order to enhance the sample concentration injected onto the column for HPLC separation, solid-phase

extraction (SPE) can be used. In online SPE, the sample is injected onto a cartridge that replaces the loop of the injection device of the chromatographic system. By switching the valve, the enriched sample is transferred directly onto the separation column. The advantage of online SPE-LC coupling is the direct enrichment of analytes on a cartridge in the HPLC system excluding light and oxygen.

A new online SPE-LC technique in which both the trace enrichment and the separation are performed on one single short HPLC column (10–20 mm in length) is called the SSC (single short column) approach. By performing online sample enrichment before LC-NMR analysis, analyte detectability may be significantly improved. The hyphenation of this approach with NMR spectroscopy can reduce the effective analysis time necessary for separation and structure elucidation. As in conventional LC-NMR coupling,

Figure 7 ^1H NMR spectra (600 MHz) of (A) all-*trans*, (B) 9-*cis* and (C) 13-*cis* zeaxanthin.

stopped-flow as well as continuous-flow experiments are possible. The higher concentration of sample is advantageous for continuous-flow LC-NMR experiments. For online SSC-NMR, 10 mL of a $5\ \mu\text{g mL}^{-1}$ mixture was loaded on to a $12.5 \times 4.6\ \text{mm}$ i.d. C_{18} short column and separated on-column with the eluents (A) acetonitrile–0.05% phosphoric acid and (B) water–0.05% phosphoric acid 30 : 70 (v/v) at a reduced flow rate of $0.3\ \text{mL min}^{-1}$ and transferred to the NMR spectrometer. Figure 8 shows the contour plot of the separation of ibuprofen, fenoprofen and naproxen.

In the case of these drugs, the differences between the structures can be determined by the signals in the aromatic region, so the structure of the separated compounds can easily be assigned by the aromatic

resonances. Whereas naproxen is a substituted naphthalene derivative, fenoprofen and ibuprofen both contain a phenyl ring which is meta-substituted in the case of fenoprofen and para-substituted in ibuprofen. For unambiguous structural elucidation, different rows could be extracted from the contour plot to obtain conventional ^1H NMR spectra, as shown in Figure 9 for ibuprofen.

GPC-NMR Coupling

One of the most impressive advantages of continuous-flow ^1H NMR spectroscopy is the direct monitoring of the change in the microstructure of polymers and in the chemical composition of copolymers during GPC. In the case of synthetic polymers, the amount of

Figure 8 ^1H NMR chromatogram (contour plot, 400 MHz) of an SPE-HPLC separation of ibuprofen, fenopropfen and naproxen.

available sample is not limited and GPC is not sensitive to peak dispersion effects. A NMR flow cell with a detection volume of 120 μL with a 400 MHz spectrometer yields adequate signal-to-noise values within a reasonable resolution time of 8 s.

One example shows the possibilities of GPC-NMR coupling and is typical of a multitude of similar prob-

lems in the chemical industry. Two styrene-butylacrylate copolymers were synthesized under similar conditions, but the physical properties of the copolymers differed. Conventional polymer analysis failed to distinguish between the samples. In both cases the chemical composition and microstructure were identical.

Figure 9 ^1H NMR spectrum of ibuprofen extracted from the SPE-HPLC-NMR run depicted in Figure 8.

Figure 10 Stacked plot (400 MHz) of the GPC-NMR separation of a styrene-butylacrylate copolymer.

A GPC separation of 100 μL of a 7.5% copolymer solution was performed with a 250×40 mm GPC column using dichloromethane as eluent at a flow rate of 0.4 mL min^{-1} . Sixteen transients were co-

added, defining a time resolution of 8.4 s. The Fourier-transformed spectrum results in a row in the two-dimensional plot of ^1H chemical shifts versus retention times (Figure 10).

Figure 11 Selected rows of the GPC-NMR separation of a styrene-butylacrylate copolymer (Figure 10) showing signals from the aliphatic and aromatic spectral region.

Figure 12 Styrene-butylacrylate copolymer composition versus GPC elution time. (A) Latex A; (B) Latex B.

The methyl group and oxymethylene signals of the acrylate (A) and the aromatic resonances of the styrene (S) units can be used in an online GPC-NMR run to derive information about the molecular weight dependence of the chemical composition.

Within one separation run, up to 128 rows were accumulated, resulting in an overall acquisition time of 42 min. Three selected rows are depicted in **Figure 11**, showing the varying intensities of the CH_3 signals of butylacrylate at 0.85 p.p.m. versus the aromatic signal of styrene at 7 p.p.m. for one copolymer sample.

Thus, the copolymer composition can be directly determined from the elution curves of both signals at any row of the chromatogram. The results from the GPC-NMR coupling for both samples are shown in **Figure 12**. The copolymers show a completely different behaviour in their dependence of the chemical composition on molecular weight.

This example demonstrates the great time-saving nature of the hyphenation of chromatography with NMR spectroscopy. To yield the same information as in the online GPC-NMR run, 128 fractions of the GPC separation would have to be collected and 128

routine ^1H NMR spectra recorded. Whereas the GPC-NMR data were obtained within less than 1 h, offline separation and NMR examination would take at least 3 h.

SFC-NMR and SFE-NMR Coupling

A separation technique employing nonprotonated solvents is SFC, using CO_2 . For SFC-NMR experiments a pressure-stable flow cell has been developed using a sapphire tube instead of glass (**Figure 1B**). At a temperature of 323 K and a pressure of 161 bar, high resolution continuous-flow NMR spectra in supercritical CO_2 can be obtained.

This is demonstrated in **Figure 13**, showing the ^1H NMR spectrum of ethylbenzene in supercritical CO_2 . Often, SFC-NMR separations can be performed with a pressure gradient. Thus, different isomers of vitamin A acetate are easily separated (**Figure 14**).

Supercritical CO_2 can also be used for supercritical fluid extraction (SFE) purposes. As an example, **Figure 15** shows the ^1H NMR spectrum of piperin extracted from black pepper at a temperature of 370 K.

Figure 13 ^1H NMR spectrum (400 MHz) of ethylbenzene in supercritical CO_2 .

Figure 14 Contour plot (400 MHz) of the separation of vitamin A acetate stereoisomers in supercritical fluid CO_2 . Reprinted from *Journal of Chromatography A*, 761, with permission from Elsevier Science.

Capillary Separations

The above examples clearly show the great advantage of combining efficient separation techniques with NMR detection for the solution of complex analytical problems. In all the applications described, analytical columns (250×4.6 mm) together with sample quantities in the μg range and HPLC analysis times of up to 30 min were employed.

However, there is an increasing need for high-throughput screening and analysis of mixtures containing unknown compounds in the growing field of biotechnology and genetic engineering. Here, only a few nanograms of biologically active mixtures of compounds may be available, and these must be fully characterized. This task can only be performed by miniaturizing the closed-loop separation identifica-

tion system, combining capillary separation technique with nanolitre-scale NMR spectroscopy.

Whereas capillary techniques are already well developed in the field of separations, nanolitre NMR spectroscopy is still in its infancy. Various hardware approaches exist to record NMR spectra on the nanolitre scale. One is the use of a solenoid coil directly attached to the fused silica capillary. The other employed by our group is the application of a microprobe with a double-saddle Helmholtz microcoil. The capillary is fixed within the microcoil in the z -direction of the cryomagnet. This approach has advantages and disadvantages. Because the capillary is inserted within the coil, it can be easily exchanged to meet other separation problems but this design has the inherent disadvantages that the filling factor (the ratio of the coil versus the sample volume) is lower in

Figure 15 ^1H NMR spectrum (400 MHz) of piperin extracted from black pepper.

Figure 16 Stopped-flow capillary ^1H NMR spectrum of a vitamin A dimerization product recorded within a capillary (detection volume 200 nL).

comparison to a design where the coil is directly fixed to the capillary. Solenoid coils with a perpendicular orientation to the B_0 direction of the cryomagnet result in a threefold increase in sensitivity in comparison with the Helmholtz microcoil design; however, the currently developed approaches suffer from susceptibility-induced line broadening due to the solenoidal coil fixing to the fused silica capillary. This design has already been improved by the application of a susceptibility-matching fluid and shows potential for further optimization. On the other hand, the orientation of the capillary within the z -direction of the B_0 field has the tremendous advantage that the NMR signal half-width is not affected when electroosmotic flow-driven separation techniques (CE, CEC) are performed. Here, the induced magnetic field of the current within the capillary has no component in the z -direction of the cryomagnet. Thus, a vertically oriented Helmholtz microcoil is a feasible design, at least for capillary separations.

Coupling of capillary HPLC rather than conventional separation techniques with NMR has several distinct advantages. The reduced solvent consump-

tion allows the use of the deuterated solvents, thus rendering elaborate solvent suppression unnecessary. If only a small amount of sample is available, higher concentrations of analyte in the detection cell are obtained when the column dimensions are small. Currently obtained sensitivity levels of this design are in the 500 ng range with acquisition times of some seconds.

One of the first practical results obtained by online capillary HPLC-NMR coupling was the structure elucidation of a vitamin A derivative. The structure of the dimers of vitamin A acetate, so-called kitols, was unknown for a long time because these compounds are sensitive to UV irradiation and to air. The classical procedure of isolation, removal of the extraction solvent and resolution in a deuterated solvent resulted in many isomerization products. By combining a capillary separation together with NMR microcoil detection, structure elucidation of a previously unknown kitol was possible. **Figure 16** shows the capillary ^1H NMR spectrum of the unknown kitol, indicating that the resolution is sufficient to obtain all necessary coupling constants, whereas the hump

Figure 17 Contour plots of (A) CHPLC and (B) CEC separation of alkylbenzoates: 1, methyl; 2 ethyl; 3, propyl; 4, butyl; 5, pentyl benzoate; ACN, acetonitrile.

(signal line width) at the height of the ^{13}C signals must be further optimized.

A further example is the online CE-NMR and online CEC-NMR separation of alkylbenzoates. Figure 17 shows the contour plot of the separation performed in the CHPLC and the CEC mode. It is evident from the CEC-NMR contour plot that all compounds are baseline-separated, resulting in distinct NMR rows in the two-dimensional display.

This example shows the great power of CHPLC, CE and CEC-NMR to derive unambiguous information of substances in complex organic molecules. The first steps towards a high-throughput separation system have already been made. For the successful performance of real-life applications, NMR sensitivity must be improved. If NMR probes with 1 ng sensitivity become available, an increasing number of capillary separations coupled with nanoscale NMR will be performed in many applications.

Partition Chromatography (Liquid-Liquid)

C. Wingren and U.-B. Hansson,
Lund University, Lund, Sweden

Introduction

Partition or liquid-liquid chromatography (LLC) is a powerful separation technique which has been successfully used for the separation and analysis of

Figure 1 Schematic illustration of LLC. IU, international units; V_R , retention volume.

a wide variety of sample types, including water-soluble and oil-soluble compounds, ionic and nonionic compounds, as well as biopolymers such as nucleic

acids and proteins. The basis of LLC is the distribution of sample molecules between two immiscible liquid phases, a stationary phase and a mobile phase (Figure 1). In conventional LLC, the stationary phase is mechanically held to a support by adsorption. In liquid chromatography (LC), the most widely used supports are those with chemically bonded organic stationary phases. This may be described as a separate LC method: bonded-phase chromatography (BPC).

LLC offers unique selectivity for various samples since a wide range of liquid phases can be used (Table 1). In normal-phase LLC, the support is coated with a polar stationary phase, whereas a relatively nonpolar solvent is used as mobile phase. In reversed-phase LLC, the two LLC phases are interchanged so that the less polar liquid is now the stationary phase and the polar liquid is the mobile phase. LLC systems composed of aqueous/aqueous, aqueous/organic or organic/organic solvents can be used, depending on the particular separation problem. A variety of supports have been used (Table 2), but silica-based matrices appear to be best suited for LLC.

The sample molecules are distributed between the stationary and mobile phases depending on their physicochemical properties and the properties of the

LLC, liquid-liquid chromatography; BPC, bonded-phase chromatography.

phases (and support). In the case of compounds, the separation is generally based on the type and number of substituent groups and by differences in molecular weight (up to about 2000 Da). Hence, LLC is very useful for the separation of homologues and mixtures of compounds of different functionality. Biopolymers (nucleic acid fragments) can be separated mainly owing to differences in molecular weight (up to about 4000 base pairs). In the case of proteins, conditions can be designed in such a way that differences in their overall exposed surface properties are detected. In fact, LLC has proved to be a unique tool for protein analysis, that is for purification and fractionation, detection and separation of conformational isomeric forms, examination of surface properties related to biological specificities and for providing information about the events upon binding of ligand and about possible ligand-induced conformational changes. In this article, we describe the use of LLC for the separation and analysis of compounds, nucleic acids and proteins, focusing on the latter group.

Separation of Compounds

A variety of compounds including detergents, drugs, insecticides, metal chelates, pesticides, phenols, sac-

charides, steroids and vitamins, some of which are shown in Table 3, have been successfully separated using LLC. LLC provides a wide range of separation selectivity since several different liquid-liquid systems can be used. In the case of normal-phase LLC, a number of separations have been performed using either β, β' -oxydipropionitrile (BOP), or one of the various polyethylene glycols (PEGs) as stationary phase. Both liquids are useful for the same type of compounds, although the PEGs may be more selective for alcohols, and BOP is preferred for basic compounds such as amines. Normal-phase LLC is used for more polar, water-soluble compounds, and the solute elution order is similar to that observed in adsorption chromatography. In reversed-phase LLC, cyanoethyl-silicone, hydrocarbon polymers and squalene, among others, have been used as stationary phases. Reversed-phase LLC is generally used to separate compounds with poor water solubility, i.e. non-polar and organic-soluble compounds.

Besides the binary liquid systems normally used in LLC, ternary liquid-liquid systems have also been found useful (Table 1). Such systems are obtained from binary liquid systems by adding a third component (cosolvent) that is miscible with both phases. Either of the two resulting phases can be used as

Table 3 Applications of LLC for separation of compounds

<i>Approach</i>	<i>Application</i>	<i>Examples</i>
Normal-phase LLC	Separation of compounds containing metals	Radioactive metals Isomers of cobalt complexes involved in synthesis of vitamin B ₁₂ Metal- β -diketonates Platinum-metal complexes
	Determination of compounds in biological samples	Vitamins K ₁ and E in serum Phosphatidylcholine in serum 2,4,6-Triiodophenol and other iodinated derivatives in serum Flumequine and 7-flumequine in serum
	Analysis of drugs in food products	Flumethasone pivalate in serum Methyl prednisolone in milk N-Nitrosamines in extract of pork
	Determination of compounds in environmental samples	Pesticides, e.g. mosquito larvacide in salt ponds Insecticides, e.g. imidacloprid in water and soil
	General separations and determinations	Penicillin derivatives Steroids, e.g. derivatized urinary 17-ketosteroids Coumarins Phenols Dinitrophenylhydrazine derivatives Ethylene oxide oligomers
Reversed-phase LLC	Determination of compounds in biological samples	Ritonavis Enoxacin and 4-oxyenoxacin in plasma and tissue Tacrine and its metabolites in plasma and urine Nucleotides in different tissues and body fluids
	Separation of important organic chemical	Antioxidants Plasticizers Nonionic organic dyes
	General separations and determinations	Fat-soluble vitamins, e.g. vitamins A, D, E and K Aromatics Paraffins Olefins and diolefins

LLC, liquid-liquid chromatography.

stationary phase, with the other as mobile phase. As an example, the ternary system formed by water/ethanol/2,2,4-trimethylpentane has been found to be very useful for the separation of many compounds including metal chelates, pesticides and steroids.

Several different supports can be used, but silicas and diatomaceous matrices appears to be best suited. These supports are inert, and have relatively large pores so as to allow ready access of the sample molecules to the stationary phase contained within the porous structure. It may be more convenient to use bonded-phase packings, the main advantage being that they are quite stable, since the stationary phase is chemically bound to the support and subsequently cannot be easily removed in use.

The separation of compounds by LLC is generally based on the type and number of substituent groups and by differences in molecular weight. This is exemplified by the fact that ethylene oxide oligomers (7-14 ethylene oxide units) can be separated by differences in number of functional groups, naphthalene

derivatives by differences in compound type, and 2,4-dinitrophenylhydrazine derivatives (C₂ to C₆) by differences in molecular weight (Table 3).

Modern LLC have been used to separate several biologically important natural and synthetic compounds, including cortisol, derivatized urinary 17-ketosteroids and free underivatized steroids. Many compounds containing metal atoms have been separated using LLC, such as radioactive metals, isomers of cobalt complexes involved in the synthesis of vitamin B₁₂, metal- β -diketonates and platinum metals complexes. Moreover, LLC has also been frequently used for determination of specific compounds in biological samples, as for example vitamins K₁ and E in serum, phosphatidylcholine in serum, 2,4,6-triiodophenol and other iodinated derivatives in serum, and flumequine and 7-flumequine in plasma.

In addition, LLC has been used to analyse drugs in various food products, e.g. flumethasone pivalate in cream, methyl prednisolone in milk and N-nitrosamines in extract of pork. Various derivatives of

penicillin have also been separated using LLC. Moreover, LLC has been used to separate and determine a number of pesticides and insecticides, such as imidacloprid in water and soil.

Reversed-phase chromatography has been used to separate mixtures of fat-soluble vitamins (vitamins A, D, E and K); mixtures of aromatics, paraffins, olefins and diolefins; chlorinated benzenes; and fused-ring aromatics. A wide variety of important organic chemicals such as antioxidants, plasticizers and nonionic dyes has been separated using LLC. Reversed-phase chromatography has also been used to determine compounds in biological samples, including ritonavir, an HIV protease inhibitor, enoxacin and 4-oxyenoxacin in plasma and tissue, and tacrine and its metabolites in plasma and urine. Another important area of application is the separation of nucleotides, nucleosides and bases that are used to examine a variety of biomedical problems.

Separation of Biopolymers

The classical version of LLC uses combinations of an organic and an aqueous or two organic liquid phases, which limits its application to small molecules without defined secondary or tertiary structure. However, the use of LLC for separation of large active biomolecules such as nucleic acids and proteins became possible (at least in theory) when P.-Å. Albertsson succeeded in developing aqueous-aqueous two-phase systems made up of two 'incompatible' water-soluble polymers such as PEG and dextran. Finding suitable supports for these systems was for a long time a major problem, however. Several attempts were made to adsorb the bottom phase onto supports made of agarose beads, polyethers immobilized on Sepharose, silicates and cellulose. The problem was solved by W. Müller in 1986 by combining the affinity of polyacrylamide for the dextran-rich bottom phase of the PEG/dextran system with the mechanical strength of hydrophilic vinyl (LiParGel) or silica (LiChrospher Diol) particles (Table 2). LLC, or LLPC (liquid-liquid partition chromatography), was then intro-

duced as a method for the separation of biopolymers. This technique was later developed further with respect to sensitivity, selectivity and reproducibility by U.-B. Hansson and co-workers, turning it into a powerful tool for protein analysis in particular. It has recently also been shown that dextran-grafted agarose beads (Superdex) can be used as a support for LLPC. LiParGel 650 has been used for the analysis of small as well as of large proteins while LiParGel 750 has mostly been used for the analysis of nucleic acids. LiChrospher-Diol 100 has been used for the analysis of small proteins ($< 100\,000$ Da) while proteins of a wide range of sizes have been analysed on LiChrospher-Diol 1000 or 4000 columns. Superdex is suitable for the analysis of small proteins ($< 100\,000$ Da).

Buffered phase systems formed by polyvinyl pyrrolidone (PVP)/dextran, polyvinyl alcohol (PVA)/dextran and PEG/salt solutions have been used for LLPC, but the PEG/dextran systems are by far the most frequently used (Table 1). A serious drawback of the PEG/dextran systems is, however, the incompatibility between PEG and some proteins such as immunoglobulins. Concentrations of PEG greater than 3% can be used to precipitate antibodies. However, this incompatibility can be partly overcome by adding appropriate salts. IgG can, for example, be solubilized in PEG/dextran systems at pH 7.0, i.e. near its isoelectric point, in the presence of 100 mmol L^{-1} betaine ($\leq 0.8\text{ mg mL}^{-1}$) or 0.1 mol L^{-1} glycine and 0.1 mol L^{-1} sodium chloride ($\leq 2\text{ mg mL}^{-1}$). Hence, the PEG/dextran systems are, for the moment, the obvious choice of two-phase system for LLPC of biopolymers, whereas the usefulness of other phase systems remains to be elucidated.

Nucleic Acids

LLPC in aqueous two-phase systems has been successfully used for DNA fractionation by size, topology and by base sequence, as well as for the fractionation of 'soluble' and ribosomal RNAs (Table 4). Hence, LLPC may provide resolutions unattainable by any other method.

Table 4 Separation of nucleic acids by LLPC

Separation according to:	Examples
Size	DNA fragments, linear relationship for fragments up to about 4000 base pairs Various RNAs from natural sources, e.g. soluble RNAs from tomato plants Ribosomal RNA up to about 30S
Base composition	<i>Eco</i> RI generated fragments from λ DNA Calf thymus DNA
Topology	Fractionation of circular DNAs

LLPC, liquid-liquid partition chromatography.

Fractionation of DNA restriction fragments by size can be performed with DNA fragments up to at least 4000 base pairs (Table 4). Mainly two-phase systems formed by PEG 8000/dextran 500 have so far been applied (Table 1). The separation can be greatly improved by applying a salt-exchange gradient. Side effects, possibly caused by slightly hydrophobic properties of the supports, may strongly influence the fractionation of DNA. Although the influence of the supports on DNA may be obvious, as in the case of proteins (see below), the general applicability of the matrices is not invalidated as the interactions may be exploited as an additional parameter for separation.

DNA may be fractionated according to base composition or sequence using PEG-bound AT- or GC-specific DNA ligands consisting of basic dyes (Table 4). In this way, these ligands will prefer the PEG-rich mobile phase and are subsequently able to shift the partitioning of matching DNA towards this phase. As in the case of DNA, RNA may also be fractionated by LLPC in aqueous two-phase systems due to differences in size. Also large (ribosomal) RNA ranging up to 30 S can be fractionated by LLPC. The high solubility of RNAs in the PEG/dextran systems is also advantageous.

Proteins

The way in which a protein molecule is distributed between the two phases in a given PEG/dextran system depends on its three-dimensional structure and general surface properties and is described by its partition coefficient, K_c (the ratio of the concentration of the molecule in the top phase to that in the bottom phase). Thus, partitioning in aqueous PEG/dextran

two-phase systems offers a unique means of separating proteins in solution with respect to their overall exposed surface properties. In addition, the method is mild so that the conformation of a partitioned protein is not likely to be disturbed.

As in the case of DNA separation, the supports may (strongly) influence the fractionation of proteins. This is illustrated in Figure 2, where LLPC on these supports resulted in different elution profiles for polyclonal IgG, i.e. the supports influenced the partitioning of immunoglobulins in different ways. The exact nature of the observed interactions is still not clear, but they may be determined by the conformation of the molecules together with the properties of the support with respect to pore size and polyacrylamide/dextran coating. Although ideal partitioning is desirable, the general applicability of the matrices is not invalidated as the interactions can be exploited as previously mentioned.

Separation

LLPC can be used to separate a wide variety of proteins including enzymes, hormones, immunoglobulins, serum proteins and transport proteins, some of which are shown in Table 5. LLPC has been successfully used for separations that have previously been difficult, for instance the separation of molecules with similar molecular weight and pI values such as α -1-antitrypsin and albumin, and corticosteroid-binding globulin and a sex hormone-binding globulin. Moreover, LLPC may replace the need of other conventional separation techniques, since LLPC, in contrast to most of these methods, is able to separate proteins owing to differences in several physicochemical properties. As for example, proteins in human sera, which can be separated in a multistep procedure by using a combination of several other techniques such as precipitation, ion exchange chromatography, gel filtration and electrophoresis, can be separated in a single step by LLPC. Furthermore, proteins that can be separated by differences in pI values, as for example isoforms of lactate dehydrogenase and malate dehydrogenase, can be separated by LLPC. In addition, monomeric and dimeric forms of HSA that can be separated by gel filtration and proteins that may be separated by hydrophobic chromatography can also be separated by LLPC. Thus, LLPC in aqueous polymer two-phase systems offers new possibilities to separate proteins in a single step and/or to obtain fractionation that is not readily achieved by other techniques.

Fractionation

LLPC can be used to fractionate proteins and may provide a selectivity and sensitivity unattainable by any other chromatographic method. Some

<i>Separation problem</i>	<i>Example</i>	<i>LLPC results/comments</i>
Complex system	Proteins in human serum Proteins in goat, sheep, dog and horse serum Proteins in mouse ascites	A single step separation achieved; previously separated in a multistep procedure using a combination of several other methods
Proteins with similar M_r and pI	α -1 antitrypsin and HSA CBG and SHBG from human serum	
Proteins with different pI	Isoforms of LDH Isoforms of MDH	LLPC is able to separate proteins due to differences in 'several' physicochemical properties and may thus replace the need of many conventional separation techniques
Proteins with different M_r Proteins with different hydrophobicity	Monomers and dimers of HSA Human IgG with different relative hydrophobicity	
General separations	Myoglobin, peroxidase, BSA and OVA Cyt c, HSA, β -lactoglobulin, lysozyme, MB, ovotransferrin, OVA and peroxidase ADH, GDH and ferritin ADH, FDH and LDH Transferrin, IgG and HSA	

ADH, alcohol dehydrogenase; BSA, bovine serum albumin; CBG, corticosteroid-binding globulin; Cyt c, cytochrome c; FDH, formate dehydrogenase; GHD, glucose 6-phosphate dehydrogenase; HSA, human serum albumin; LDH, lactate dehydrogenase; LLPC, liquid-liquid partition chromatography; MB, myoglobin; MDH, malate dehydrogenase; OVA, ovalbumin; SHBG, sex hormone-binding globulin.

representative examples, including enzymes and antibodies, are given in **Table 6**. The usefulness of LLPC for this purpose was highlighted in recent studies where several enzymes known to exist in equilibrium between two allosteric forms were analysed. Yeast alcohol dehydrogenase, liver alcohol dehydrogenase, the heart and muscle isoforms of lactate dehydrogenase and two types of hexokinase (fraction I and II of Kaji), are all eluted as two components by LLPC, in spite of the fact that the enzyme preparations appear

to be homogeneous when analysed by other conventional methods such as isoelectric focusing, sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and high performance liquid chromatography-size exclusion (HPLC-SE). Remarkably, an equilibrium between the two components with different surface properties for each of these enzymes can be demonstrated by LLPC. These results show that LLPC can be used to detect and even separate different conformational isometric forms of unliganded enzymes. It

Table 6 Fractionation of proteins by LLPC

<i>Proteins</i>	<i>LLPC results/comments</i>
LADH YADH LDH-H ₄ LDH-M ₄ Hexokinase ^a	An equilibrium between two components with different surface properties detected (i.e. conformational isomeric forms)
sMDH mMDH	Two components with different surface properties detected
Polyclonal IgG Polyclonal IgA Polyclonal IgM	Several components detected
Monoclonal IgG	An equilibrium between at least two components with different surface properties detected (for six of 57 antibodies; conformational isomeric forms?)

^aSimilar results were obtained for two types of hexokinase, fraction I and II of Kaji. LADH, liver alcohol dehydrogenase; mMDH, mitochondrial malate dehydrogenase; sMDH, cytoplasmic malate dehydrogenase; LDH-H₄, heart lactate dehydrogenase; LDH-M₄, muscle lactate dehydrogenase; LLPC, liquid-liquid partition chromatography; YADH, yeast alcohol dehydrogenase.

Figure 3 LLPC of 57 monoclonal IgG antibodies containing 95% IgG and homogeneous with respect to their physicochemical properties as determined by HPLC-SE, SDS-PAGE and IEF. The LLPC chromatograms are schematically illustrated in (A), which represents 51 of the IgGs, and (B), which represents six of the IgGs.

may be of interest to note that the LLPC fractionations of the mitochondrial and cytoplasmic isoforms of malate dehydrogenase, the allosteric mechanisms of which are still unclear, also result in two components with different surface properties.

Immunoglobulins are another group of proteins that have been successfully fractionated using LLPC (Table 6 and see below). Purified polyclonal immunoglobulins of IgG, IgM or IgA class can be fractionated into several components using LLPC. In the case of IgG and IgA, it is of a special interest to note that the fractionation is not subclass-related since the

elution profile of each of the subclasses is similar to that of the applied polyclonal antibody population. Surprisingly, some monoclonal antibodies have been found to be fractionated into at least two components by LLPC, in spite of the fact that they are homogeneous with respect to their immunochemical and physicochemical properties (Figure 3). This phenomenon was observed not only for IgG antibodies but also for IgA and IgM myeloma proteins. Recent LLPC experiments have demonstrated that six of 57 monoclonal IgG antibodies seem to exist in an equilibrium between at least two components with different surface properties. Thus, LLPC seems to be able to detect and separate conformational isomeric forms of unliganded antibodies. It has been suggested (using different kinetic techniques) that a tenth of all antibodies may indeed display conformational isomerism.

Specificity

LLPC can be used to examine differences in surface properties of proteins (mainly immunoglobulins) related to their biological specificities; some illustrative examples are given in Table 7.

In early LLPC experiments, polyclonal rabbit IgG antibodies with different specificities were found to exhibit different partition properties (expressed as a partition coefficient, K_c). Since no IgG subclasses have been reported for rabbit IgG, i.e. their Fc parts are likely to be the same, these results indicated that LLC had detected differences in surface properties between IgGs located on structures in their Fab parts. This exciting finding was followed up by more extensive studies in which large sets of well-characterized monoclonal IgG antibodies were analysed by LLPC. These studies clearly showed that there was no correlation between K_c and a single immunochemical and physicochemical property such as light-chain and

Table 7 Examination of surface properties of proteins related to biological specificities using LLPC

pAbs, polyclonal antibodies; mAbs, monoclonal antibodies; Ag, antigen; HSA, human serum albumin; DNP, 2,4-dinitrophenol; T₃, triiodothyronine; T₄, thyroxine; NIP, 5-iodo-4-hydroxy-3-nitrophenyl; K_c , the ratio of the concentration of the molecule in the top phase to that in the bottom phase; LLPC, liquid-liquid partition chromatography.

Figure 4 Comparison of the partition properties of (A) intact IgG with those of the corresponding Fab fragments and (B) Fc fragments from one IgG subclass with those of the other subclasses. The partition properties are expressed as a partition coefficient, K_c . The correlation coefficient was (A) 0.80 ($P < 0.05$). (B) The 95% confidence limits of the K_c values are given.

heavy-chain isotypes, charge, size and shape. However, a significant linear correlation between the partition properties of intact IgG1, 2, 3 and 4 and their corresponding Fab fragments was detected (Figure 4). In contrast to the Fabs, Fc fragments from IgG1, 2 and 4 displayed almost identical surface properties (Figure 4). Taken together, the results showed that the differences detected by LLPC between intact IgGs were indeed located on their Fabs.

Further studies have revealed a remarkable relationship between the partition properties of an IgG molecule and the structure of its combining site (specificity; see Table 7). In particular, monoclonal IgG antibodies with different affinities for the same antigen or directed against different antigens are eluted with different K_c values, while monoclonal IgGs with identical affinity constants for the same hapten or the same epitope on a protein are found to have identical K_c values. Moreover, chimaeric anti-NIP antibodies with identical variable regions, corresponding to the human IgG1, 2 and 4 subclasses, display identical surface properties, i.e. differences in the constant part of the heavy chains did not affect the partitioning. Thus, the surface properties of IgGs are, as detected by LLPC, dominated by those of their antigen-binding sites. Recent LLPC experiments have indicated that the antigen-binding site dominance observed for IgG is valid for all the other Ig classes and subclasses provided that antibodies only within a given class or subclass are compared with respect to exposed surfaces. Indications of a dominance of ligand-binding sites for other specific proteins, such as enzymes, have been reported. Taken together, LLPC may offer a unique possibility to screen the antigen-binding sites for differences/similarities in exposed surfaces, even in those cases when we do not know the specificity of the antibodies.

This unique property of LLPC was made use of in a recent study that showed that the LLPC profile for

polyclonal IgG antibodies isolated from the sera of patients with an autoimmune disease (primary Sjögren's syndrome) differed significantly from those of polyclonal IgG isolated from the sera of healthy individuals. These antibodies with 'unique and deviating' specificities could also be isolated by LLPC. Thus, LLPC may provide us with the means to fractionate and isolate specific antibodies 'of unknown specificities'.

Ligand Binding

Finally, LLPC can also be used to study the events upon binding of a ligand by specific proteins in solution. Some typical example, including transport proteins, enzymes and polyclonal as well as monoclonal antibodies, are given in Table 8. In many cases, LLPC can simply be used to separate the ligand-protein complex from either of the free components. This is, for example, the case for most of the enzyme-ligand and antibody-ligand complexes analysed so far.

In recent studies, the capacity of LLPC for analysis of protein-ligand complexes was demonstrated using well-characterized ligand-protein complexes where ligand-induced conformational changes are known to occur. In addition, the ligands in these model complexes are small and almost completely buried upon binding, i.e. the bound ligands themselves would not be responsible for any changes in surface properties observed upon complexation. Small changes in surface properties were detected when rabbit transferrin bound ferric ions, while no changes were observed when human transferrin (which is known to be less flexible) bound the ions. The ligand-induced transition between two conformational isomeric forms could be detected by LLPC for a large number of enzymes, including alcohol dehydrogenase, citrate synthase, glutamate-oxaloacetate transaminase, hexokinase, lactate dehydrogenase, malate dehydro-

Table 8 Examination of the events upon binding of ligand by specific proteins in solution using LLPC

Protein	Ligand	LLPC results/comments
Rabbit transferrin	Fe ³⁺	Small changes in K_c detected
Human transferrin	Fe ³⁺	No changes in K_c detected
CS	Oxaloacetate	Ligand-induced transition between two conformational isomeric forms detected

CS, citrate synthase; GAPDH, glyceraldehyde-3-phosphate dehydrogenase; GOT, glutamate-oxaloacetate transaminase; HSA, human serum albumin; LADH, liver alcohol dehydrogenase; LDH-H₄, heart lactate dehydrogenase; LDH-M₄, muscle lactate dehydrogenase; mAbs, monoclonal antibodies; LLPC, liquid-liquid partition chromatography; mMDH, mitochondrial malate dehydrogenase; sMDH, cytoplasmic malate dehydrogenase; NIP, 5-iodo-4-hydroxy-3-nitrophenacetyl; pAbs, polyclonal antibodies; PGA, 3-phosphoglycerate; PGK, 3-phosphoglycerate kinase; T₃, triiodothyronine; YADH, yeast alcohol dehydrogenase.

genase and 3-phosphoglycerate kinase. In the case of antibodies, conformational changes may occur upon binding of either hapten (T₃ and NIP) or protein antigens (HSA, IgG and transferrin) that are detectable by LLPC. The surface properties of chimaeric anti-NIP antibodies with identical variable regions, corresponding to the human IgA1, IgA2, IgE, IgG1, IgG2, IgG3, IgG4 and IgM isotypes, have been compared before and after binding of hapten. The hapten-antibody complexes were found to be eluted in a considerably narrower range of K_c values than were the free antibodies. It was concluded that conformational changes, detectable by LLPC, occurred in either IgA1, IgA2, IgE and/or IgM, but not in the IgGs, making the surfaces of the constant regions of the heavy chains of the Ig classes and subclasses more similar. Hence, LLPC may provide us with the means to examine whether ligand binding induces conformational changes in the antibody when in solution.

Almost all the antigen-antibody pair analysed by LLPC so far have formed complexes that are eluted as single homogeneous peaks by LLPC (Figure 5). Moreover, the complexes are eluted with the same value of K_c irrespective of the molar ratio of antigen to antibody at which they are formed (ranging from antigen to antibody excess). Thus, the results imply

that each antigen-antibody pair forms one type of complex with respect to exposed dominant surfaces. This is thought to be the first study reporting such a feature for antigen-antibody complexes.

Remarkably, a linear relationship between the surface properties of unliganded IgGs and their corresponding hapten-IgG complexes has been reported, and it was concluded that the surface properties of

Figure 5 LLPC of antigen-antibody complexes (AgAb) formed at different molar ratios of antigen (Ag) to antibody (Ab) (Ag : Ab = 2 : 1–0.5 : 1). Representative results obtained for one monoclonal IgG antialbumin antibody are shown.

IgG are dominated by those of its antigen-binding sites even after the specific binding of hapten or hapten-carrier at the combining sites. By contrast, the surface properties of protein-antibody complexes are not related to those of the unliganded antibodies. Instead, the surface properties of protein-IgG complexes are related mainly to those of the antigens. Depending on the type of antigen (hapten or protein), LLPC may thus be used to separate antigen-IgG complexes through differences in exposed surfaces of either the antibody combining sites or the antigen. LLPC may thus provide us with new, interesting information concerning the events upon complex formation in solution and possible ligand-induced conformational changes.

Physico-Chemical Measurements

R. P. W. Scott, Avon, CT, USA

Copyright © 2000 Academic Press

Chromatography theory establishes that the retention volume of a solute is a function of its distribution coefficient and the variance of the eluted peak is a function of solute diffusivity. Consequently, retention volume measurements can provide distribution coefficient data which, if determined over a range of temperatures, will disclose the necessary thermodynamic information that will help reveal the physical nature of the distribution process. In addition, peak dispersion measurements can furnish accurate diffu-

sion coefficients for almost any solute, in any liquid, at any chosen temperature, assuming appropriate solute solubility and temperature stability. Hence, the use of liquid chromatography to measure physico-chemical properties of a distribution system hinges on the accurate measurement of retention volumes and peak widths.

Gas chromatography retention volume measurements have been used to provide a significant amount of thermodynamic data, including standard free energies, enthalpies and entropies of distribution, together with activity coefficients. These types of physico-chemical measurements were pioneered in the late 1950s. In contrast, the use of liquid chromatography

for the same purposes has not been nearly so prevalent, although in many ways it can be a simpler and a more accurate experimental procedure.

Basic Thermodynamic Theory of Solute Distribution in Liquid Chromatography

The expression that relates the change in *standard free energy* of a solute when transferring from one phase to the other, as a function of the equilibrium constant (the distribution coefficient, K) is as follows:

$$RT \ln K = -\Delta G^0 \quad [1]$$

where R is the gas constant, T is the absolute temperature and ΔG^0 is the standard free energy change.

Now:

$$\Delta G^0 = \Delta H^0 - T\Delta S^0 \quad [2]$$

where ΔH^0 is the standard enthalpy change and ΔS^0 is the standard entropy change.

The enthalpy term represents the energy involved when the solute molecule interacts by electrical forces with a molecule of the stationary phase. However, when interaction takes place, the freedom of movement of the solute molecule is also reduced and it can no longer move in the same random manner that it did in the mobile phase. This new motion restriction is measured as an entropy change. Thus, the free energy change is made up of an actual energy change which results from the work done during the interaction of the solute molecules with those of the stationary phase, and an entropy change that accounts for the resulting restricted movement or loss of randomness, when the solute is associating with the stationary phase.

Continuing:

$$\ln K = -\left(\frac{\Delta H^0}{RT} - \frac{\Delta S^0}{R}\right) \quad [3]$$

It is seen that if the standard entropy change and standard enthalpy change for the distribution of any given solute between two phases could be calculated, then the distribution coefficient (K) and, consequently, its retention volume could also be predicted. Unfortunately, these properties of a distribution system are bulk properties that include, in a single measurement, the effect of all the different types of molecular interactions that are taking place between the solute and the two phases. As a result, it is often difficult to isolate the individual interactive contributions in order to estimate the magnitude of the overall distribution coefficient, or identify how it can be

controlled. Nevertheless, there are a number of ways in which this can be done and, in any event, the thermodynamic approach can provide valuable information with regard to the nature of the distribution.

Rearranging eqn [3]

$$\ln K = -\frac{\Delta H^0}{RT} + \frac{\Delta S^0}{R} \quad [4]$$

Bearing in mind:

$$V_r' = KV_s \quad \text{and} \quad k = \frac{KV_s}{V_m} = \frac{K}{a} \quad [5]$$

where V_r' is the corrected retention volume of the solute, V_s is the volume of stationary phase in the column, V_m is the volume of mobile phase in the column, a is the phase ratio V_m/V_s , and k is the retention factor of the solute. Thus:

$$\ln(V_r') = -\frac{\Delta H^0}{RT} + \frac{\Delta S^0}{R} + \ln(V_s) \quad [6]$$

or:

$$\ln(k) = -\frac{\Delta H^0}{RT} + \frac{\Delta S^0}{R} - \ln(a) \quad [7]$$

It is seen that a curve relating $\ln(V_r')$ or $\ln(k)$ to $1/T$ should give a straight line, the slope of which will be proportional to the standard enthalpy change during solute transfer and the intercept will be related to the standard entropy change (but will include the logarithm of the phase ratio). Thus, the dominant thermodynamic contribution to any specific distribution system can be identified from such curves.

Such curves are called van't Hoff curves and an example of two exaggerated theoretical van't Hoff curves relating $\log(V_r')$ against $1/T$ for two different types of distribution system is shown in **Figure 1**. It is seen that distribution system (A) has a large enthalpy value $[\Delta H^0/RT]_A$ and a low entropy contribution $[-(\Delta S^0/R) + V_s]_A$. The large value of $[\Delta H^0/RT]_A$ means that the distribution is predominantly controlled by molecular forces. The solute is preferentially distributed in the stationary phase as a result of the interactions of the solute molecules with those of the stationary phase being much greater than the interactive forces between the solute molecules and those of the mobile phase. Because the change in enthalpy is the major contribution to the change in free energy, the distribution, in thermodynamic terms, is said to be energy driven.

Figure 1 Van't Hoff curves for two different distribution systems. (A) Energy-driven distribution; (B) entropically driven distribution.

In contrast, it is seen that for distribution system *B* there is only a small enthalpy change $[\Delta H^0/RT]_A$, but in this case a high entropy contribution $[-(\Delta S^0/R) + V_s]_B$. This means that the distribution is not predominantly controlled by molecular forces. The entropy change reflects the loss of randomness or freedom that a solute molecule possessed when transferring from one phase to the other. The more random and more free the solute molecule is to move in a particular phase, the greater is its entropy in that phase. In system *B*, the large entropy change indicates that the solute molecules are much more restricted or their movements less random in the stationary phase than they were in the mobile phase. Because the change in entropy in system *B* is the major contribution to the change in free energy, the distribution, in thermodynamic terms, is said to be entropically driven.

Chiral separations and separations dominated by size exclusion are examples where retention and/or selectivity would be entropically controlled. However, chromatographic separations cannot be exclusively energetically driven or entropically driven, but must contain both constituents. In some cases, by careful adjustment of both energetic and entropic components, very difficult and subtle separations can be accomplished.

In most distribution systems met in chromatography, the slope of the van't Hoff curves are positive and the intercept negative. The negative value of the intercept means that the standard entropy change of

the solute has resulted from the production of a less random and more orderly system during the process of distribution into the stationary phase. More importantly, this entropy change reduces the magnitude of the distribution coefficient and attenuates solute retention. Conversely, the greater the forces between the molecules, the greater the energy (enthalpy) contribution, which increases the distribution coefficient and extends the retention. Thus, in liquid chromatography, the enthalpy and entropy changes tend to oppose one another in their effect on solute retention. In fact, there is considerable parallelism shown between the standard entropy and standard enthalpy of a series of solutes for a given distribution system.

This relationship between entropy and enthalpy has been reported many times in the literature. An example of a graph relating ΔH to ΔS is shown in Figure 2. Any increase in enthalpy indicates that more energy is used up in the association of the solute molecule with the molecules of the stationary phase. This means that the intermolecular forces are stronger and thus the stationary-phase molecules hold the solute molecules more tightly. In turn, this implies that the freedom of movement, and the random nature of the solute molecule, are also more restricted, which results in a larger change in standard entropy. It follows that, unless other significant retentive factors are present, any increase in standard enthalpy is usually accompanied by a corresponding increase in standard entropy. If the molecules of one of a pair of closely eluting isomers suffer a greater reduction in

Figure 2 Graph plotting standard free entropy against standard free enthalpy for ether (triangles), thioether (squares) and amine (circles).

freedom or randomness relative to those of the other then, providing the energy changes are similar for the molecules of both isomers, those that experience the greater entropy change will be eluted first.

The van't Hoff curves can help provide even more information on the elution process. If the slope of the $\ln(k)$ versus $1/T$ curves (i.e. the standard free enthalpies) differ for two closely eluting isomers, then the lines must eventually intercept and there must be a temperature of co-elution and a subsequent elution order reversal. This elution order reversal is often not apparent in practice, as the co-elution temperature may occur outside the temperature range over which the distribution system will function satisfactorily for chromatographic purposes. However, in such distribution systems, which will include those used in most chiral separations, the operating temperature is of paramount importance in selecting the optimum operating conditions.

The Distribution of Standard Free Energy

The standard free energy can be used to explain chromatographic retention in two different ways. Firstly, portions of the standard free energy can be allotted to specific types of molecular interactions between the solute molecules and the two phases. Secondly, the molecule can be divided into different parts and each part allotted a portion of the standard free energy. This approach allows the contributions

made by different parts of the molecule to retention to be explained. This concept was suggested by Martin in his early papers, and can be used to relate molecular structure to solute retention. An example of the second approach is as follows.

Thermodynamic Analysis of a Homologous Series

Consider the distribution of the standard free energy throughout an n -alkane molecule, allotting a portion to each methylene group and to the two methyl end-groups. Then, algebraically, this concept can be put in the following form:

$$RT \ln(V'_{r(T)}) = -n\Delta G_{(\text{methylene group})} - m\Delta G_{(\text{methyl group})} \quad [8]$$

where $\Delta G_{(\text{methylene group})}$ is the standard free energy of each methylene group, $\Delta G_{(\text{methyl group})}$ is the standard free energy of each methyl group, n is the number of methylene groups and m is the number of methyl groups ($m = 2$ for an n -alkane).

The concept will now be applied to a simple n -alkane series, the data for which was obtained on the stationary-phase n -heptadecane by Martire and his co-workers. This procedure will show how it is possible to identify the difference between the contribution of a methylene group and a methyl group to solute retention and how the difference can be explained. The curves for $\log(V'_{r(T)})$ against the number of methylene groups in each of the three n -alkanes for seven different temperatures are shown in Figure 3.

The expected straight lines are produced at each temperature and the indices of determination are very close to unity. The slope represents the portion of the standard free energy from each methylene group and each intercept represents the portion from the two methyl groups. It should be noted that the contribution of a single methyl group is seen to be significantly less than that from one methylene group. The slopes (the free energy contribution from a single methylene group, $\Delta G_{(\text{methylene group})}/RT$) and half the intercept (the contribution from one terminal methyl group $\Delta G_{(\text{methyl group})}/RT$) plotted against the reciprocal of the absolute temperature are shown in Figure 4.

These curves provide relative values for the standard enthalpy ($\Delta H_{(\text{methylene group})}/R$ and $\Delta H_{(\text{methyl group})}/R$) and standard entropy ($\Delta S_{(\text{methylene group})}/R$ and $\Delta S_{(\text{methyl group})}/R$) of the distribution for each group, the magnitude of which indicates the manner in which they interact with the stationary phase.

Despite the contribution of a methyl group to the free energy being much less than that of the methylene group, the energies of interaction (the enthalpies)

Figure 3 Graph showing $\log(V'_{(T)})$ against number of methylene groups for a series of *n*-alkanes. \square , 22.5°C; $y=0.5150x + 0.6211$, $r=1.0000$. \circ , 30°C; $y=0.4949x + 0.5737$, $r=1.0000$. \bullet , 40°C; $y=0.4706x + 0.5126$, $r=1.0000$. \triangle , 50°C; $y=0.4448x + 0.4631$, $r=1.0000$. \blacksquare , 60°C; $y=0.4216x + 0.4196$, $r=1.0000$. \blacktriangle , 70°C; $y=0.4008x + 0.3751$, $r=1.0000$. \diamond , 80°C; $y=0.3792x + 0.3399$, $r=1.0000$.

of the two groups are very similar. However, the entropy term for the methyl group is nearly 50% greater than that of the methylene group and, as this acts in opposition to the standard enthalpy contribution, it reduces the free energy associated with the methyl group by about 30% relative to that of the methylene group. This entropy difference between the two groups is due to the methylene group being situated in a chain (more rigidly held) and has,

Figure 4 Graph showing intercept and slope from $[\log(V'_{(T)})/\text{number of CH}_2 \text{ group curves}]$ for a series of *n*-alkanes against the reciprocal of the absolute temperature. Squares, CH_2 : $y=246.7281x - 0.3186$; $r=0.9999$. Diamonds, CH_3 groups: $y=235.2839x - 0.4333$; $r=0.9985$.

initially, a much lower entropy before solution in the stationary phase. In contrast, the methyl group, situated at the end of the chain, is much less restricted and thus, on interaction with the stationary phase molecules, the entropy change is much greater. It follows that the introduction of a methylene group into a solute molecule will increase its retention more than the introduction of a methyl group due to the greater change in entropy associated with the methyl group.

Thus, if different portions of the standard free energy of distribution are allotted to different parts of a molecule, then their contribution to solute retention can be revealed. Furthermore, from the relative values of the standard enthalpy and standard entropy of each portion or group, the manner in which the different groups interact with the stationary phase may also be revealed.

The Distribution of Standard Free Energy Between Different Types of Molecular Interactions

In contrast to apportioning the standard free energy between different groups in the solute molecule, it can also be divided between the different types of forces involved in the solute/phase-phase distribution. This approach has been elegantly developed by Martire in his unified theory of retention. In a simplified form, the standard free energy can be divided into portions that result from the different types of interaction, e.g.:

$$\Delta G = \Delta_{\text{dispersive}} + \Delta_{\text{polar}} + \Delta_{\text{ionic}} \quad [9]$$

The polar interactions are often divided into weak, moderate and strong interactions that have, somewhat arbitrarily, been given terms such as π - π interactions, dipole-dipole interactions and hydrogen bonding:

$$\Delta G = \Delta_D + \Delta_{\pi-\pi \text{ interactions}} + \Delta_{\text{dipole-dipole interactions}} + \Delta_{\text{hydrogen bonding}} \quad [10]$$

Nevertheless, it is important to realize that they are not different types of interaction, but are all polar interactions, electrical in nature but of different strengths. In fact, many more terms have been introduced to describe subtly different enthalpic and entropic contributions to retention. In some cases, these extra terms are often introduced to take into account many second-order effects. It must be emphasized, however, that standard free energy is a bulk property, and where a portion is allotted to a particular type of interaction, e.g. dispersive, it will include all

dispersive interactions throughout the whole molecule and not one specific interaction that arises from a particular chemical group.

This approach has been used to determine the so-called binding constants between solute and stationary phase and also to investigate complexation constants. Binding constants and complexation constants have been introduced to distribution system theory largely to account for the wide range of strengths associated with polar interactions between molecules. It follows that some discussion of the physical nature of solute distribution between phases on the molecular level is necessary. Molecules can interact with one another by dispersive forces, polar forces and ionic forces, all of which are electrical in nature. Dispersive forces occur between randomly formed transient dipoles that are continuously generated throughout the molecule. For nonpolar substances, dispersive forces are proportional to their molar volume and polarizability. Polar forces result from charge concentrations dispersed at different parts of a molecule (overall electrically neutral) and can vary widely in strength. At the extreme, the energies involved can approach that of a chemical bond, as in hydrogen bonding. Polar forces may or may not be related to the dipole moment of the substance as internal electrical compensation can take place. Consequently, as dipole moments are calculated from bulk measurements made by external electrical fields, the results are frequently not related directly to the polarity of the substance. For example, the magnitude of the apparent dipole moment of dioxane, as calculated from bulk measurements, is 0.45 Debyes. This compares with 1.15 Debyes for diethyl ether, which theoretically should be about half that of dioxane. Yet dioxane is a very polar substance, soluble in water, whereas ether is weakly polar and relatively insoluble in water. Ionic forces result from the net charges on the molecule and are not germane to this discussion.

Polar interactions can result between molecules with permanent dipoles (which are often very strong) and also between a molecule with a permanent dipole and one which is polarizable (which at the extreme can be very weak). When a polarizable molecule comes into close proximity with a molecule having a permanent dipole, the electric field from the dipole induces a counter dipole in the polarizable molecule. This induced dipole acts in the same manner as a permanent dipole and the polar forces between the two dipoles result in a polar interaction between the molecules. The part of the molecule that is negatively charged due to an asymmetric accumulation of electrons has been given the term an electron donor site, whereas the area of electron depletion in the molecules

(that balances the site of electron accumulation) has been given the term electron acceptor site. More simply, these are basically negatively and positively charged sites on the molecule. Because polar interactions have such a range of strengths, certain ranges of polarity have been assumed to be due to certain types of electrical interaction that have been given the terms nonbonding lone pair, bonding π orbital, vacant orbital, antibonding π orbital, antibonding σ orbital, all of which are based on the accepted electron configuration of the molecule. In practice, however, whatever the cause, the strength of the interaction, and thus its effect on solute retention, is directly related to the intensity of the interacting charges. From the standing of separation technology, whether the introduction of these alternative terms helps to explain the separation process is a moot point, as, even in theory, in most cases the individual effects are extremely difficult to isolate completely from one another.

Martire *et al.* developed a theory assuming that polar interactions constituted the formation of a complex between the solute and the stationary phase with its own equilibrium constant. The complex is assumed to have no vapour pressure and thus remains stationary in the column until, as a result of the equilibrium kinetics, it dissociates again into the individual components. The uncomplexed solute molecule then continues to migrate along the column until complexing again takes place. Experimental data obtained to test the theory led to the conclusion that those solutes that are retained without complexing are retained solely by dispersive forces, whereas retention by polar interactions is the result of complexing. This is one approach to the explanation of retention by polar interactions, but the subject, at this time, remains controversial. Doubtless, complexation can take place, and probably does so in cases like olefin retention on silver nitrate-doped stationary phases. However, if dispersive interactions (electrical interactions between randomly generated dipoles) can cause solute retention without the need to invoke the concept of complexation, it is not clear why polar interactions (electrical interaction between permanent or induced dipoles) need to be considered differently.

Experimental Procedures

The basic apparatus that is recommended for measuring retention volumes in liquid chromatography is shown in Figure 5.

The equipment is standard, but the column oven should be capable of controlling the column temperature within $\pm 0.1^\circ\text{C}$. In addition, some provision should be made for pre-heating the mobile phase to

Figure 5 Apparatus for measuring retention volumes.

the correct temperature before it enters the column. The pressure drop across the column is expended as heat in the column, which can result in a significant rise in column temperature. To reduce this thermal effect, the pressure drop across the column must be made minimal and thus, very low flow rates should be employed. There are two basic methods used for measuring retention volumes. The first is to use a pump having a very constant flow rate and obtain values for the retention volume by multiplying the pump flow rate by the accurately measured retention time. The second, a better method, is to make absolute measurements of retention volume, using an accurately calibrated burette connected to the detector outlet.

This arrangement renders the use of an accurate and expensive pump unnecessary and eliminates any residual variation in pump flow rate that may still exist. The experimental procedure is as follows. The burette is read, the sample injected and the pump started. The detector output is observed and when a peak emerges, the pump is shut off at the peak maximum. The system is allowed a minute to reach equilibrium and the burette is read again. The difference between the two readings is taken as the retention volume being measured. Each retention volume should be measured in duplicate (preferably in triplicate) and any two measurements should not differ by more than 2%. After each retention volume measurement, the burette is drained to waste, until just above the lowest calibration, a few minutes allowed for drainage to be complete, and the next retention volume can then be measured. The retention volume is taken as the average of the replicates. The dead vol-

ume can be measured in a number of different ways and the numerous problems associated with dead volume measurement have been discussed in detail by Alhedai *et al.*

There are two column dead volumes that are used in liquid chromatography, the dynamic dead volume and the thermodynamic dead volume. The dynamic dead volume is the volume of the mobile phase that is actually moving, and is usually taken as the retention volume of an ionic salt such as sodium nitroprusside which, due to ionic exclusion, cannot enter the pores of the stationary phase or support. This value is used in peak dispersion theory calculations. The thermodynamic dead volume is taken as the total volume of mobile phase in the column. It is best obtained by weighing the column full of mobile phase, passing a gas through the column, and drying to constant weight. The difference between the full and empty column is taken as the thermodynamic dead volume. The retention volume of the solvent (or one component of a solvent mixture) carrying an isotopic atom can also be employed but a refractive index detector will probably be needed as the detector.

If the mobile phase consists of a mixture of solvents, then an approximate value for the thermodynamic dead volume can be taken as the retention volume of one pure component of the mixture. To minimize errors in dead volume measurement by this method, the retention factor (k) of any solute being examined should be in excess of 5. The corrected retention volume can be taken as the difference between the average retention volume of the solute and the dead volume. An example of a set of results relating corrected retention volume to the reciprocal of the absolute temperature is shown in **Figure 6**.

The information given in **Figure 6** can be used in a number of ways. It is clear that enantiomer B has the higher standard free entropy and is thus the enantiomer that interacts more closely with the chiral stationary phase. The closer association of the B enantiomer with the stationary phase also results in a greater standard free enthalpy and the curves, V_r against $1/T$, will thus have different slopes. Consequently, the two curves will intercept and, despite having different standard free entropies and enthalpies, there will be a temperature of co-elution above which the order of elution will be reversed. In this case, the elution order reversal was not observable as the co-elution temperature was above the maximum permissible for the particular stationary phase.

The linear equations resulting from a curve fit to the data will allow the retention factors (k) and the separation factor (α) of the two enantiomers to be calculated for any temperature. The analysis time, column length and minimum efficiency are a function

Figure 6 Graph plotting log (corrected retention volume) against the reciprocal of the absolute temperature for a pair of enantiomers separated on vancomycin. Squares, enantiomer A: $y = 631.1694x - 0.5614$; $r = 0.9992$. Circles, enantiomer B: $y = 725.8641x - 0.8116$; $r = 0.9993$.

of the retention factors and separation factor (α) of the two enantiomers. Thus, with an appropriate computer program, the optimum temperature, necessary efficiency and the optimum column length that will provide the minimum analysis time can be calculated from the data given in Figure 6. Finally, values for the standard free enthalpy and entropy for different solutes on different distribution systems can provide an insight into the nature and strength of the molecular interactions involved, which can then be related to molecular structure.

Chromatographic Methods for Measuring Diffusion Coefficients and Molecular Weights

The use of chromatography techniques to measure diffusion coefficients and molecular weights can be used very effectively where other techniques are difficult, cumbersome or time-consuming to employ. Diffusion coefficients are readily obtained by measuring the dispersion of a solute band in the liquid of interest as it passes through an open tube, but certain precautions must be taken. This technique follows directly from the theory of dispersion in open tubes developed by Golay. The van Deemter equation that describes dispersion occurring in a packed column can be used in a similar way to obtain an approximate estimation of the molecular weight of an eluted solute from a packed column.

Diffusion coefficients from dispersion measurements in open tubes Chromatographic techniques employ-

ing open tubes can be used very effectively to determine diffusion coefficients in liquids which, in turn, have been shown to be simply related to molecular weights. This work was pioneered in 1976 by Grushka and Kikta, who showed that the diffusion coefficient of a substance in a specific liquid (the diffusivity) could be determined by measuring its dispersion after passing through a cylindrical tube. According to the theory of band dispersion in an open cylindrical tube, as developed by Golay, the variance per unit length H of the solute band eluted from an open tube carrying no stationary phase is given by:

$$H = \frac{2D_m}{u} + \frac{r^2u}{24D_m} \quad [11]$$

where u is the linear velocity of the liquid through the tube, D_m is the diffusivity of the solute in the liquid and r is the radius of the tube.

Now, if $u \gg D_m/r$, then:

$$H = \frac{r^2u}{24D_m} \quad [12]$$

or:

$$D_m = \frac{r^2u}{24H} \quad [13]$$

As the value of D_m is generally less than 2.5×10^{-5} and the tube diameter is usually about 0.010 in i.d. then, $D_m/r < 10^{-3} \text{ cm s}^{-1}$, thus the condition $u \gg D_m/r$ is easily met in practice.

The apparatus is simple and consists of a solvent reservoir, a pump, a sample valve, the open tube and a suitable detector. The open tube should be jacketed by a larger tube containing circulating water from a thermostat. Temperature control should be $\pm 0.2^\circ\text{C}$. In order to ensure all measurements are accurate, however, some important conditions must be met. The sample valve must be an internal loop valve and have a capacity less than $0.2 \mu\text{L}$; the detector cell must have a small volume certainly not greater than $5 \mu\text{L}$ and preferably less; the open tube must be connected directly to the detector cell with no intervening connecting tube (all commercial detectors have significant lengths of connecting tube between the column and the detector cell, and this connecting tube must be removed or bypassed so that the open tube is connected directly to the cell). These requirements are necessary to ensure that any extra tube dispersion is insignificant compared with that occurring in the open tube. In addition, solute diffusivity is pressure-dependent and thus low flow rates must be used to ensure a minimum pressure drop across the tube. Finally, there must be no radial flow introduced

in the open tube, as this aids diffusion and gives false high values. Consequently, the tube must be perfectly straight between the sample valve and the detector cell. Even a slight curve will produce radial flow and significantly increase the diffusivity as measured, and give false high values.

The band width is measured at the points of inflection at 0.6065 of the peak height. If manual measurements are used, the chart speed should be adjusted so that the peak width is at least 1 cm. The width should be measured with a comparator, reading to an accuracy of ± 0.1 mm. At least three replicate runs should be made and the three replicate values of efficiency should not differ by more than 2%. If the data acquisition system has software that will directly measure column efficiency, then this can be used providing its accuracy is carefully checked manually. Noise on the detector can often introduce inaccuracies that are less likely to occur with manual measurement.

Katz and Scott employed the technique to determine the diffusivities of 70 different solutes in an ethyl acetate-*n*-hexane solvent mixture. Using the data they also demonstrated a relatively simple relationship between the diffusivity and the molecular weight of the solute:

$$\begin{aligned}\frac{1}{D_m} &= A + BV^{1/3}M^{1/2} \\ &= A + BM^{0.833}d^{-0.333}\end{aligned}\quad [14]$$

where V is the molar volume of the solute, M is the molecular weight of the solute, A and B are constants for the solvent system employed, and d is the density of the solute.

Employing the values they obtained for the diffusivities of the different solutes, the relationship between diffusivity and molecular weight as given in eqn [14] is demonstrated by the curves relating $(1/D_m)$ against $(V^{1/3}M^{1/2})$, shown in Figure 7. It is clear that an approximate value of the molecular weight of an eluted solute can be obtained from the diffusivity of the solute which in turn will be related to the band width or the dispersion of the peak.

This procedure has been extended further by Katz to the measurement of high molecular weight materials such as polypeptides and proteins using a packed column. In the first instance, Katz found it necessary to identify the function of k which was included in the resistance to mass transfer term of the van Deemter equation. This was achieved by relating the difference between measured H values (the variance per unit length of the column) and the multipath term, to the reciprocal of the solute diffusivity, using solutes of

Figure 7 Graph relating the reciprocal of the diffusivity to the product of the cube root of the molar volume and the square root of the molecular weight. Courtesy of Elsevier Science.

known diffusivities. The system was then used to determine the molecular weight of a number of high molecular weight materials. The values obtained were not exceptionally accurate but were practically useful.

In summary, the distribution coefficient and the thermodynamic properties of a distribution system can be easily measured by liquid chromatographic procedures. In addition, information can be gained about the nature of the distribution system and the molecular interactions involved. It is also possible to determine diffusion coefficients and approximate values for the molecular weights of eluted solutes by peak width measurements. Such data, however, may require some rather complex calibration procedures and the results, particularly with respect to the solute molecular weight, may have a precision of only $\pm 20\%$.

Liquid chromatography (LC) involves the separation of the components of a mixture by virtue of differences in the equilibrium distribution of the components between two phases: one which is a liquid (the mobile phase) and moves in a definite direction, the other which is stationary (the stationary phase). Modern LC using very small particles and a relatively high inlet pressure is referred to as high performance liquid chromatography (HPLC).

Stationary Phase

An advantage of LC over gas chromatography is in the variety of types of stationary and mobile phases which may be used, allowing the separation of such diverse molecular species as pharmaceuticals, agrochemicals, proteins, inorganic and organic ions and biopolymers. The use of a stationary phase with a liquid coated physically onto an inert solid support (partition chromatography) has been superseded by the use of a liquid chemically bonded on to the solid support (bonded-phase chromatography). Ideally, the support does not contribute to the separation process, but its particle size and surface properties have a profound effect on the efficiency of the process.

The term liquid–solid chromatography (LSC) covers a range of techniques:

- adsorption chromatography, when the stationary phase is an active solid (e.g. silica, alumina or a polymer) and separation is based on adsorption affinities between the sample molecules and the surface of the active solid
- ion chromatography, which uses an ion exchange medium
- exclusion chromatography using a stationary phase (e.g. a polymer or porous silica) which separates according to molecular size and shape
- affinity chromatography, which utilizes the unique biological specificity of the analyte and ligand interaction with the stationary phase

Liquid chromatography can be carried out within a tube (column chromatography) or on a flat sheet of material (planar chromatography) such as a sheet of paper (paper chromatography) or a layer of stationary phase coated on to a support, e.g. a glass or plastic sheet (thin-layer chromatography, TLC). In column chromatography, the stationary phase (liquid plus support) can fill the whole inside volume of the tube (packed column) or be concentrated along the inside wall of the tube, leaving an unrestricted path for the mobile phase in the middle of the tube (open tubular or capillary column). The term column will be used in a general sense to apply to both column and planar chromatography.

A significant difference between GC and HPLC is the permeability of columns used. The permeability (κ) is a measure of flow resistance:

$$\kappa = \eta L \bar{u} / \Delta P = \eta L^2 / \Delta P t_M \quad [1]$$

where η = viscosity, L = column length, \bar{u} = average mobile phase velocity, ΔP = pressure drop across the column and t_M = residence time for an unretained substance.

Introducing the particle diameter (d_p), the flow resistance parameter (ϕ) is given by:

$$\phi = d_p^2 / \kappa \quad [2]$$

Permeable columns are the most desirable and typically ϕ values are ~ 500 for spherical microparticles.

Mobile Phase

In LC the mobile phase is often called the solvent, but since solid samples have to be made into a solution by dissolution in a sample solvent, the use of the term solvent for the mobile phase may cause confusion. However, in order to avoid solubility prob-

lems when the sample is injected on to the column, it is safest, whenever possible, to make the sample solution using the same liquid as is to be used as the mobile phase, in which case no confusion should arise.

The time taken by a sample to pass through the column (the total elution/retention time: t_R) is a function of the mobile-phase velocity and the volume of mobile phase required to elute the component from the column, the total retention volume (V_R), is given by:

$$V_R = F \times t_R \quad [3]$$

where F is the volume flow rate of mobile phase measured at the column outlet at ambient temperature (T_a) and ambient pressure (P_a). Since column temperatures are usually close to ambient, temperature corrections on flow rate are rarely applied. Volume flow rates are measured from the time required to collect a given volume of mobile phase or with an electronic flow meter. Unlike gas chromatography, liquid mobile phases can be considered as incompressible and the flow rate is uniform throughout the column.

Linear flow rates (\bar{u}) are measured from the retention time, called the hold-up time, of an unretained substance (t_M), i.e. one which moves at the same velocity as the mobile phase:

$$\bar{u} = L / t_M \quad [4]$$

where L is the column length.

However, whereas in gas chromatography it is reasonable to assume that a substance like nitrogen or helium will have negligible solubility in the stationary phases used, in LC finding a species which is soluble in the mobile phase and will not have at least some retention on the stationary phase – therefore giving too high a hold-up time – often proves difficult. Furthermore, with a porous stationary phase, excluded components (not uncommon with mobile phases with a high water content) do not access the total mobile-phase volume and may actually run ahead of the mobile phase, giving too low a hold-up time.

Porosity can be used to verify the hold-up time. The total porosity (ε) of a column is the volume fraction occupied by the mobile phase:

$$\begin{aligned} \varepsilon &= \frac{V(\text{column}) - V(\text{packing material})}{V(\text{column})} \\ &= \frac{4F(\text{mL min}^{-1})t_M(\text{s})}{d_c^2(\text{mm})L(\text{mm})} \end{aligned} \quad [5]$$

where F = volume flow rate, d_c = column diameter and L = column length. For a totally porous material $\varepsilon \sim 0.75$ and ~ 0.4 for porous layer beads.

Thus, values of the hold up time obtained for a given component should give these values according to the type of packing material used. Values < 0.75 indicate the molecule is excluded from the pores of the stationary phase, and values > 0.75 indicate that retention on the stationary phase has occurred.

Choice of mobile phase is fundamental to the separation in LC. Mixtures of solvent, with up to four components are commonly used, so that as well as the chemical nature of the components, miscibility considerations are important. Physical properties, such as viscosity, volatility, refractive index and UV absorption can also limit the choice of mobile phases.

Modes of Liquid Chromatography

Analytical LC is always carried out by elution chromatography where the mobile phase is passed continuously through the column and the sample is fed (or injected) into the system as a finite plug. If the conditions for the analysis are optimized, the sample components can be completely separated from each other. Placing a detector at the end of the column, which responds to some property of the sample, produces a trace (the chromatogram) which is a plot of detector response against time.

If the stationary phase is more polar than the mobile phase, the term normal-phase chromatography is used, and if the stationary phase is less polar than the mobile phase the term reversed-phase chromatography is used.

The General Elution Problem

A typical chromatogram for the separation of a mixture of components which illustrates the character-

istics of chromatography, and is often referred to as the general elution problem, is shown in **Figure 1**.

The properties which the chromatogram illustrates and which must be explained by any theory of chromatography are:

- The components of the mixture elute from the column at different times (retention).
- Peak widths increase with retention time (peak shape and broadening).
- The separation of pairs of peaks is not constant (column resolution).

Chromatographic Retention

Retention parameters are measured in terms of times, mobile-phase volumes or retention factors (k) (previously called capacity factors: k'). If the flow rate is constant, the volumes are proportional to times, e.g. t_R (time) is analogous to V_R (volume).

If a mixture is chromatographed, the time taken for a component to be eluted from the column, the (total) retention time (t_R), is measured from the moment of injection to the appearance of the peak maximum. This, together with the width of the peak measured at the baseline (w) or at half peak height (w_h), and the elution of an unretained peak, are important parameters in chromatography and are illustrated in **Figure 2**, which shows the separation of a two-component mixture eluting with retention times $(t_R)_1$ and $(t_R)_2$, with an unretained component (retention time, t_M).

The retention volume (V_M) of an unretained peak (where $V_M = F \times t_M$) is also called the mobile-phase volume and equals the volume (both inter- and intra-particle) available to the mobile phase in the column.

The adjusted retention time/volume (t'_R/V'_R) is the total elution time/volume minus the retention

Figure 1 The general elution problem.

Figure 2 Separation of a two-component mixture showing retention parameters. See text for details.

time/volume of the mobile phase:

$$t'_R = t_R - t_M; \quad V'_R = V_R - V_M \quad [6]$$

The unretained peak, which has no affinity for the stationary phase and does not exhibit exclusion, passes through the column at the same speed as the mobile phase. A substance which shows affinity for the stationary phase moves through the column more slowly than the mobile phase and is said to be retained. The ratio of the two velocities is known as the retardation factor (R):

$$R = \frac{\text{rate of movement of retained peak}}{\text{rate of movement of mobile phase}} \quad [7]$$

A retained component spends time in both the mobile phase (t_M) and the stationary phase (t_S) and retention time t_R is given by:

$$t_R = t_M + t_S \quad [8]$$

The time spent in the stationary phase is dependent on the distribution coefficient (K_c) such that $t_S = K_c V_S$. If C_S and C_M are the concentrations of a component in the stationary phase and mobile phase respectively, the distribution constant is given by:

$$K_c = C_S/C_M \quad [9]$$

The rate of movement of a component through the column is inversely proportional to the distribution constant, i.e. a substance with a high concentration in

the stationary phase (a high distribution coefficient) moves slowly through the column. Components of a mixture are, therefore, separated only if their distribution coefficients differ. Using volumes rather than times we can write:

$$V_R = V_M + K_c V_S \quad \text{or} \quad V'_R = K_c V_S \quad [10]$$

which is the fundamental equation for chromatography, neglecting the effects of nonlinearity of the sorption isotherm and band broadening.

In adsorption chromatography the stationary-phase volume is replaced by the surface area (A_S) of the stationary phase, and the distribution coefficient is changed to the adsorption coefficient (K_A).

An alternative expression (the retention factor: k) for the distribution of a sample component is in terms of the relative number of moles (n) of a component in the stationary and mobile phases, such that:

$$k = n_S/n_M = K_c \cdot (V_S/V_M) \quad [11]$$

$$R = \frac{\text{amount of solute in the mobile phase}}{\text{amount of solute in mobile + stationary phases}} \quad [12]$$

$$\begin{aligned} \text{or } R &= n_M/(n_M + n_S) \\ &= 1/(1 + k) \end{aligned} \quad [13]$$

Substituting the retention factor into the equation:

$$V_R = V_M + K_c V_S \quad \text{gives} \quad V_R = V_M(1 + k) \quad [14]$$

or using retention times:

$$t_R = t_M(1 + k) \quad [15]$$

and on rearrangement:

$$k = (t_R - t_M)/t_M \quad [16]$$

This last expression is widely used as a simple way of expressing retention from values easily measured from the chromatogram, and without the need to measure flow rates.

Since:

$$t_M = L/\bar{u} \quad [17]$$

we can write:

$$t_R = \frac{L}{\bar{u}} (1 + k) \quad [18]$$

Hence the retention time is directly proportional to the column length and inversely proportional to the linear flow rate of the mobile phase.

Peak Shape and Broadening

The variation of solute concentration in the stationary phase with solute concentration in the mobile phase, at constant temperature, is known as the sorption isotherm. Simple chromatographic theory assumes a linear isotherm relationship, i.e. the distribution coefficient is constant. Under these conditions the

retention time is independent of sample concentration and the peak moves with a constant speed. Given a peak profile with plug-shape distribution on injection, this shape should be maintained as the peak passes through the column to emerge at the exit. However, because of longitudinal diffusion in the direction of flow, the peak takes on a Gaussian distribution. If the isotherm relationship is nonlinear (e.g. Langmuir or anti-Langmuir), the distribution coefficient is not constant but varies with solute concentration and there is a distribution of solute velocities across the peak, which is described as tailing or fronting. This relationship between isotherm shape and peak shape is illustrated in Figure 3.

The width of a chromatographic peak is a function of the column efficiency, expressed as the plate number (N), calculated from the following equations depending on the value used for the peak width (Figure 2):

$$N = (V_R/\sigma)^2 = (t_R/\sigma)^2 = 16(t_R/w_b)^2 = 5.545 (t_R/w_h)^2 \quad [19]$$

where σ is the standard deviation of the Gaussian peak.

The column length divided by the plate number gives the plate height or height equivalent to a theoretical plate (H) and normalizes the plate number for column length: $H = L/N$. The concept of plates in chromatographic theory (the plate theory) is by analogy with the distillation process and represents a notional length of the column in which the solute molecules reach a distribution equilibrium. Thus,

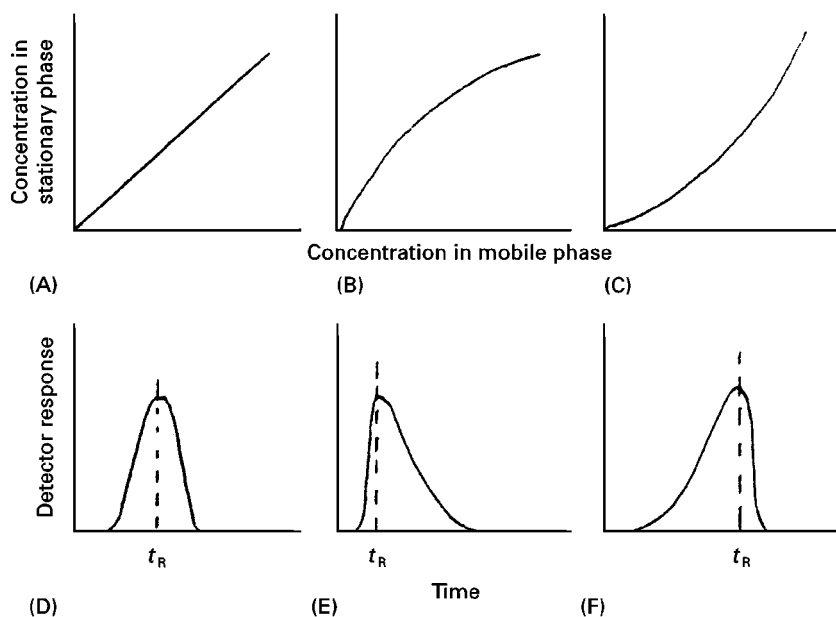

Figure 3 Isotherm shape and their effect on peak shape and retention times. (A) Linear; (B) Langmuir; (C) anti-Langmuir; (D) Gaussian; (E) tailing; (F) fronting.

a large number of theoretical plates corresponds to an efficient column.

Consideration of the chromatographic process as controlled by equilibrium gives a satisfactory explanation of chromatographic retention in term of the distribution coefficients, but in considering band broadening a different approach is required – the rate theory of chromatography. This was first applied by van Deemter, Klinkenberg and Zuiderweg to gas chromatography, but has been extended to include LC. As the solute band passes through the column the band width increases and the solute is diluted by the mobile phase. Although the process of fluid flow is complex, three main contributions to band broadening (i.e. to the variance (σ^2) of the Gaussian peak) may be recognized: the multipath effect (formally called eddy diffusion), molecular diffusion and mass transfer.

The Multipath Effect (the *A* term)

Molecules flowing through a packed bed of stationary phase will take paths of different lengths resulting in a small difference in retention times. This has the effect of broadening the band by an amount dependent on the particle diameter (d_p), such that:

$$A = 2\lambda d_p \quad [20]$$

The packing constant (λ) is an empirical term depending on the shape (spherical or irregular) of the packing material and the packing efficiency, and reaches a minimum value $\cong 0.5$. For open tubular columns there is no *A* term.

Longitudinal Molecular Diffusion (the *B* term)

Solute molecules diffuse in a longitudinal direction (i.e. along the column axis) according to Fick's law of diffusion. The amount of band spreading is directly proportional to the coefficient of diffusion (D_M) of the solute molecules in the mobile phase, and inversely proportional to the mobile-phase flow rate. An obstruction factor (ψ) is introduced to account for the restricted diffusion in a packed bed.

Hence:

$$B = 2\psi D_M/\bar{u} \quad [21]$$

Longitudinal molecular diffusion is only significant in LC if small ($< 10 \mu\text{m}$) stationary-phase particles are used at low mobile phase velocities and with a relatively high solute diffusion coefficient.

Mass Transfer (the *C* terms)

In LC, band broadening due to mass transfer is a complex process involving both the stationary and mobile phases. Two processes are responsible for

band broadening in the stationary phase (stationary phase mass transfer: C_s). The first of these processes involves the finite rate of mass transfer across the mobile-phase/stationary-phase interface. At the head of the column the solute is distributed between the stationary and mobile phases according to the value of the distribution coefficient. As the band moves down the column, solute at the leading edge of the band is continually meeting new stationary phase, into which it dissolves. To maintain the equilibrium, solute will dissolve from the trailing edge of the band out of the stationary phase back into the mobile phase. Because this process is not instantaneous the band is broadened. The second process involves the statistical distribution of the rates of diffusion of individual molecules in the stationary phase, resulting in small differences in the time that individual molecules spend in the stationary phase. A fast-moving mobile mass sweeps the zone more rapidly through the column and accentuates the band broadening as does a greater film thickness (d_f) of stationary phase. A higher rate of solute diffusion in the stationary phase (D_s) will decrease the band broadening so that:

$$C_s = q \cdot \frac{k}{(1+k)^2} \frac{d_f^2 \bar{u}}{D_s} \quad [22]$$

where q is a configuration factor depending on the nature of the stationary phase.

In adsorption chromatography, the C_s term is expressed in terms of the adsorption/desorption kinetics of the solute molecules on the stationary phase.

Band broadening in the mobile phase also results from two different processes. Moving mobile phase mass transfer (C_M) results from frictional forces which modify the laminar flow profile across a channel between two particles, resulting in a higher flow velocity in the centre of the channel. Stagnant mobile-phase mass transfer (C_M^*) is the result of slow diffusion of solute molecules in and out of the pores of a porous stationary phase. The overall mobile-phase mass transfer can be represented by the expression:

$$C_M = f(d_p^2, d_c^2) \cdot \bar{u}/D_M \quad [23]$$

where d_p is the particle diameter and d_c is the column diameter, D_M the solute diffusion coefficient in the mobile phase and \bar{u} is the linear velocity.

Giddings, recognizing that molecules are free to diffuse from one flow path into another, introduced the idea of 'coupling' the multipath term (*A*) and the mobile-phase mass transfer (C_M) so that the variation of the plate height (*H*) with \bar{u} is then given by:

$$H = B/\bar{u} + C_s \bar{u} + C_M^* \bar{u} + \{1/A + 1/C_M \cdot \bar{u}\}^{-1} \quad [24]$$

The contribution of the various terms to the total plate height is illustrated in Figure 4.

Extra-Column Band Broadening

So far, we have only considered band-broadening processes within the chromatographic column itself but, in assessing the overall performance of the system, the instrument as a whole is important. Thus, the injection system, detector and connecting tubing all contribute to the overall peak shape. The objective for injection is to get the sample on to the column in as narrow a plug as possible. Slow transfer of the sample from the injector to the column causes peak broadening and peak tailing. Large dead volumes in the detector can lead to remixing of components and deterioration of the separation as well as dilution of the sample peaks, reducing detection limits. The peak broadening in an open tube (radius r and length L), volume flow rate F , and for a solute with diffusion coefficient D_M is given by:

$$\pi r^4 FL / 24 D_M \quad [25]$$

In particular, short lengths (< 30 cm) of narrow-bore (~ 0.01 in) connecting tubing should be used.

Column Resolution

Chromatographic separation is only achieved when there is a difference in the distribution coefficients of two components, i.e. the molecular interactions (dispersion forces, dipole interactions and hydrogen-

bonding forces) between the sample molecules and the stationary phase are sufficiently different. More fundamentally it is the free energies of distribution $\Delta(\Delta G^\theta)$ of the components of a mixture which must differ. It can be shown that:

$$\Delta(\Delta G^\theta) = -RT \ln \alpha = -RT \ln [(K_c)_2 / (K_c)_1] \quad [26]$$

A stationary phase which produces a large degree of separation is said to have high selectivity. The separation of two components (1 and 2) is expressed by the relative retention (α):

$$\alpha = t'_{R(2)} / t'_{R(1)} = V'_{R(2)} / V'_{R(1)} = k_{(2)} / k_{(1)} = K_{C(2)} / K_{C(1)} \quad [27]$$

If one of the pair is a standard substance, the symbol used for relative retention is r . Having achieved a separation, it is necessary to prevent remixing of the components and the ability to achieve this is a function of the column efficiency, as measured by the plate number. The combined effects of stationary-phase selectivity and column efficiency are expressed in the peak resolution (R_s) of the column:

$$R_s = \frac{(t_R)_2 - (t_R)_1}{(w_1 + w_2)/2} \quad [28]$$

A value of $R_s = 1.5$ is normally considered to represent baseline separation for Gaussian-shaped peaks. To achieve the maximum peak resolution, both high selectivity and column efficiency (giving narrow bands) are required.

Figure 4 The van Deemter plot for LC and the variation of the terms A , B , C_s and C_M with flow rate. See text for details.

Increased resolution can always be achieved by an increase in column length since the peak separation (Δt_R) is proportional to the distance of migration down the column, but peak width is only proportional to the square root of the migration distance. The penalty for this, however, is longer retention times and an increased inlet pressure of mobile phase.

The Purnell equation shows how peak resolution is related to the retention factor (k), the plate number (N) and the relative retention (α):

$$R_s = \frac{\sqrt{N_2}}{4} \cdot \frac{(\alpha - 1)}{\alpha} \cdot \frac{k_2}{1 + k_2} \quad [29]$$

where the subscript 2 refers to the second peak.

Conditions for obtaining maximum values of the plate number have already been discussed. In LC the relative retention is governed by the nature of the mobile phase as well as the stationary phase. In order to obtain a satisfactory separation, a balance must be achieved between the interactions (dispersion forces, dipole-dipole interactions, dipole-induced-dipole interactions, H-bonded forces), represented in Figure 5 by an interaction triangle.

If the interactions between the sample and stationary phase are too strong, the retention times will be excessively long, whereas if the interactions between sample and mobile phase are too strong, retention times will be too short. Modifications to the mobile phase (e.g. the addition of ion-pairing agents, chiral molecules) may also be used to change stationary-phase-mobile-phase interactions.

The interactions are maximized in the concept of 'like has an affinity for like'. Thus, for a sample which contains predominantly nonpolar species, a nonpolar stationary/mobile phase will optimize the dispersion forces, and polar interactions will be absent. For polar samples a polar stationary/mobile phase will maximize both dipole-dipole interactions and dipole-induced-dipole interactions and the effect of dispersion forces will be reduced. At least a partial separation can be achieved with α values as low as 1.01,

Figure 5 The interaction triangle in LC.

but values in the range 1.5–3.0 are preferable but above values of about 5.0 little additional resolution is achieved.

Peak resolution increases rapidly with increasing k values, but at values > 10 the term $k_2/(1 + k_2) \rightarrow 1$ and the term plays no further part in the resolution. The use of k values < 1 gives very short retention times and poor resolution, so that the optimum for k is between 1 and 10. The retention equation $t_R = L/\bar{u}(1 + k)$ shows that retention times are a function of both the mobile-phase velocity (\bar{u}) and the retention factor.

In LC, temperature has little effect on retention, because of the relatively small values of the enthalpies of solution involved. The van't Hoff equation describes the change in equilibrium constant with temperature and if the phase ratio (V_s/V_M) is independent of temperature we can also write for the retention factor:

$$\frac{d \ln k}{dT} = \frac{\Delta H}{RT^2} \quad [30]$$

where ΔH is the enthalpy of solution (or adsorption) from the mobile phase to the stationary phase.

The main use of temperature control is to increase the reproducibility of retention times, and to increase column efficiency through the effect of temperature on viscosity and diffusion. The first choice to be made is, therefore, the choice of chromatographic mode (normal phase or reversed phase) and the stationary phase. In practice, the reversed-phase mode can be used for samples with a wide range of polarities and is usually the mode of choice. Bonded stationary phases with a hydrocarbon chain attached to the silica surface (e.g. Si-C₁₈) are widely used; the polarity of the phase may be modified by introducing functional groups (e.g. -CN, -NH₂) into the chain.

To select the mobile phase, the concept of solvent strength and polarity is utilized. A strong solvent is one which causes a sample to elute rapidly from the column. Various measures of solvent strength are used:

- solvent strength parameter (E°), based on the adsorption energies of the solvent on alumina
- solvent polarity parameter (P'), based on experimental solubility data which reflects the proton acceptor, proton donor and dipole interactions of the solvent molecule
- the Hildebrand solubility parameter (δ), which measures dispersion and dipole interactions, and hydrogen acceptor and donor properties.

Figure 1 for the general elution problem also shows values of k for different zones of the chromatogram. With low k values ($k < 1$) the peaks are eluted too rapidly and there is no time for separation. With high k values ($k > 10$) elution times are long, the peaks are

broad and the peaks are over-resolved. This problem can be corrected using the technique of gradient elution which is analogous to temperature programming in gas chromatography. Assuming that the chromatogram in Figure 1 was obtained isocratically using a binary mixture of 50% methanol–water, it would be possible to choose a lower solvent strength mixture (e.g. 25% methanol–water) and then increase the methanol content (say to 75%) over a given period of time. This would have the effect of increasing the k values for the early peaks and decreasing the k values for the later peaks, the object being to get all peaks in the optimum region, where k is between 1 and 10. Modern computer-controlled liquid chromatographs have the facility to use isocratic periods and linear and nonlinear gradient programs with multiple ramps to give better control over k values.

The retention equation also indicates that a similar effect could be achieved using the analogous technique of flow programming and changing the mobile-phase flow rate. Having optimized the retention factors by gradient elution, it may still be necessary to alter the selectivity of the system in order to achieve a complete separation. Using the solvent strength parameters, solvents can be classified into eight groups according to their proton acceptor, proton donor and dipole properties and a triangular graph constructed. Solvents are selected from the different classes in order to maximize differences in their properties (bearing in mind the need for solvent compatibility, e.g. miscibility).

For the solvent polarity parameter the value of P' for a binary mixture (AB) is given by:

$$P'_{AB} = \phi_A P'_A + \phi_B P'_B \quad [31]$$

where ϕ_A and ϕ_B are volume fractions of A and B.

From this relationship it is possible to calculate mixtures of solvents having the same solvent strengths, e.g. 45% methanol–water, 52% acetonitrile–water, 37% tetrahydrofuran–water all have the same solvent strength and would give the same retention factors (k), but because of their different proton acceptor/donor and dipole properties they would give different selectivities (α values).

A satisfactory separation is achieved when all three terms in the Purnell equation are optimized.

Future Developments

The theory of LC is well established but a greater understanding of the complexities of fluid flow may lead to improved column performance. Developments in the understanding of the interactions between solute molecules and stationary/mobile phases and the preparation of new stationary phases (e.g. chiral phases) will lead to new applications. Developments in the field of capillary electrophoresis may erode some of the traditional fields of application of LC, e.g. in the analysis of ionic compounds. Developments in instrumentation with new coupled techniques are also a possibility. The most likely area for further development is in the area of data handling and instrument control using the newer breed of computers.

The analytical potential of any separation method is greatly increased when it is combined with a detector that gives qualitative and quantitative information about the separated components. Fourier transform infrared spectrometry (FTIR) has therefore been increasingly used as a detector for supercritical fluid chromatography (SFC), ever since Shafer and Griffiths published the first paper on combined SFC/FTIR in 1983. These researchers recognized that SFC's main application area was the analysis of thermally labile compounds and those too involatile or polar to be analysed by gas chromatography (GC). Furthermore, they realized the potential compatibility of SFC with FTIR detection due to the use of a mobile phase such as carbon dioxide, which has extensive regions of transparency in the infrared (IR) region. Once demonstrated, various SFC/FTIR interfaces were rapidly developed, due to extensive interest from both academia and industry.

The development of FTIR spectrometry itself has also been key to the success of combined SFC/FTIR. In FTIR spectrometry, IR radiation which has been modulated is passed through the sampling area and is detected by a highly sensitive mercury cadmium telluride (MCT) detector. The interferograms, which are plots of IR intensity versus time, are signal-averaged at intervals of less than 1 s and stored on the hard disk of the spectrometer's computer system. The data system then executes a Fourier transform of the interferograms, which are compared against a background to produce an IR spectrum of absorbance (or percentage transmittance) versus wave number. In comparison to a dispersive IR spectrophotometer, which only allows one frequency of radiation to be detected at any one monochromator setting, a FTIR allows all frequencies to be detected simultaneously. Thus, not only can IR absorbance spectra be measured rapidly, a large number of spectra can also be co-added to

increase the sensitivity of the technique (Fellgett's advantage). FTIR is therefore fast enough to measure a number of complete IR spectra in real time during the elution of a chromatographic peak. The FTIR has several other advantages over dispersive instruments. The interferometer in an FTIR instrument uses a gas laser to reference the position of the moving mirror. As a result, these instruments are characterized by high resolution and highly accurate and reproducible frequency determinations, which is particularly useful when spectra have to be co-added or subtracted for background correction (Connes' advantage). FTIR optics also provide much large energy throughput (Jacquinot's advantage) and have minimal light scattering (stray light advantage) in comparison to dispersive instruments that incorporate gratings and narrow slits. In summary, FTIR spectrometry can be used as a highly informative, nondestructive and universal detector for SFC. Since absorption bands can be assigned to individual functional groups in organic molecules, the technique is especially useful for selective detection and the identification of unknown analytes.

When used as a detector for SFC, FTIR is however constrained by two major problems: mid IR absorption by most chromatographically compatible mobile phases and relatively low FTIR sensitivity compared to many of the other commonly used chromatographic detectors. To minimize these problems, various ingenious interfaces have been explored. These designs appear to vary greatly, but they can be classified by essentially two approaches: flow cell interfaces, where the column effluent and analytes are monitored, in real time, by the IR beam as it passes through a high pressure flow cell, and mobile-phase elimination interfaces where the analytes are collected on an IR transparent window (for subsequent IR analysis) as the mobile phase depressurizes at the column outlet. **Table 1** documents the main advances in the development of SFC/FTIR, and the following discussion considers both interface types in more detail.

Flow Cell SFC/FTIR

The flow cell approach involves connecting a high pressure flow-through cell at the end of the separation column and positioning the flow cell in the FTIR beam so that the analytes can be monitored in real time as they elute from the column and flow through

Table 1 Key advances in the development and application of flow cell and mobile elimination interfaces for SFC/FTIR

Year	Development
<i>Flow cell approach</i>	
1983	First demonstration of flow cell SFC/FTIR using carbon dioxide as the mobile-phase (Shafer and Griffiths)
1985, 1986	Demonstration of packed column SFC/FTIR with 10 μL flow cell Evaluation of carbon dioxide and Freon-23
1986	First use of xenon as a mobile phase for capillary SFC/FTIR
1987	Development of Gram-Schmidt orthogonalization for removing baseline drift from reconstructed chromatograms as a result of pressure programming the mobile phase
1988	Introduction of commercial thermostated 1.4 μL flow cell for capillary SFC/FTIR Application to thermally labile compounds such as pesticides and vitamins demonstrated Detection limit for caffeine determined to be ~ 2 ng
1989	Development of 800 nL flow cell for use with 50 μm i.d. capillary columns Use of make-up gas to minimize band broadening in flow cell studies
1990	Stopped flow SFC/FTIR used to improve signal-to-noise ratio of flow cell measurements
1991–94	Comparison of xenon and carbon dioxide as mobile phases for SFC/FTIR
1994	Investigation of 500 nL flow cell for use with 50 μm i.d. capillary columns Practicability of multihyphenated SFC-UV-FTIR system demonstrated
<i>Mobile phase elimination approach</i>	
1986	First demonstration of packed column SFC with deposition on moving KCl plate. Offline diffuse reflectance IR spectra measured from analytes (Shafer and Griffiths; Pentoney)
1986	Use of FTIR microscope to measure IR spectra from 150 μm diameter spot deposited from capillary SFC and restrictor on to a ZnSe plate (Pentoney <i>et al.</i>)
1988	Demonstration of offline mobile phase elimination approach to polymer additives, phenolic carboxylic acids, steroids, polycyclic aromatic hydrocarbons
1989	Comparison of IR sampling techniques evaluated for SFC/FTIR Conventional transmission sampling confirmed to give best sensitivity, reproducibility and adherence to Beer's law
1992	Adaption of first commercial online direct deposit GC/FTIR interface for SFC/FTIR
1995	Performance of real-time direct deposition SFC/FTIR interface characterized Identifiable spectra from 600 pg caffeine demonstrated (Norton and Griffiths) Application to sulfanilamides, silicone oligomers, polyethylene glycol and nonyl phenol oligomers, herbicides

the cell. The IR absorbance is directly proportional to the concentration of the sample in the chromatographic peak that is flowing through the cell at any given time, according to the Beer-Lambert law. A flow restrictor is usually placed after the cell to maintain high pressure in the flow cell, but since FTIR is nondestructive, additional detectors such as a flame ionization detector may be connected in series after the flow cell. A schematic diagram of a SFC/FTIR with a flow cell interface is shown in **Figure 1**. One of the main advantages of online FTIR detection is that chromatograms based on total or selected IR absorbance of the organic molecules can be reconstructed using the Gram-Schmidt algorithm. The retention time data obtained from the Gram-Schmidt reconstructed (GSR) chromatogram is complemented by structural information provided by interpreting IR spectra of the separated components, or by compar-

ing them with a spectral library. The major disadvantage of this interface is the low detection sensitivity obtained, due to the fact that in a dynamic system only a limited number of spectra can be measured as an analyte peak passes through the flow cell.

Flow Cell Compatible Supercritical Mobile Phases

Traditionally, analytes that are incompatible with GC have been separated by liquid chromatography (LC). However, most LC solvents absorb so strongly in the IR region of the spectrum that flow cells with very short pathlengths (typically 100–500 μm) must be used to prevent the solvent bands from completely obstructing wide regions of the spectrum. Detection limits are therefore very high (>20 times higher than in GC/FTIR). One of the advantages of supercritical carbon dioxide, the most commonly used SFC mobile phase, is that it has extensive regions of transparency

Figure 1 Schematic diagram of SFC/FTIR system with a flow cell interface.

in the IR region of the spectrum, making it more compatible for flow cell SFC/FTIR. However, not all functional groups can be detected and in these cases xenon or other fluids have been used.

CO₂ has two strong infrared-active fundamental vibrational modes, the antisymmetric stretching band that is centred at approximately 2350 cm⁻¹ (ν_3) and the bending mode near 668 cm⁻¹ (ν_2). The symmetry-forbidden symmetric stretch (ν_1) is centred at about 1390 cm⁻¹. These bands obscure the IR spectrum from 2137 to 2551 cm⁻¹ and below 800 cm⁻¹, as shown in Figure 2A. The intensity of ν_1 is enhanced by Fermi resonance with $2\nu_2$, so that two bands at 1390 and 1285 cm⁻¹ are observed in the spectrum. In SFC, the mobile phase is typically programmed from a low density to a higher density to increase the solvent power of the fluid and elute progressively more involatile analytes. As the density of the CO₂ is programmed upwards, these Fermi resonance bands also increase in intensity, as shown in Figure 2B, but are generally not a problem to deal with, as they may be subtracted from the spectra of eluting components if short cell pathlengths (<10 mm) are used. These two Fermi modes also interact with ν_3 to generate a very intense doublet, ($\nu_1 + \nu_3$) and ($\nu_3 + 2\nu_2$), that

obscures the 3504–3822 cm⁻¹ region. Consequently, vibrational modes of functional groups such as the O–H stretch (3500–3800 cm⁻¹), C≡N stretch (2100–2200 cm⁻¹), C–Cl stretch (600–800 cm⁻¹) and aromatic C–H out-of-plane bending modes that absorb below 750 cm⁻¹ cannot be detected in CO₂. It should also be pointed out that the position of absorption bands in the spectra of compounds measured in carbon dioxide vary with the pressure and temperature of the mobile phase. For example, variations up to 10 cm⁻¹ have been observed in spectra measured in liquid versus supercritical CO₂. Modifications of intensity distribution and band width variations were also reported. As a result, the SFC/FTIR spectra obtained using a flow cell are very similar but may not be identical to vapour-phase spectra. However, SFC is generally applied to involatile materials for which

Figure 2 (A) IR spectrum of carbon dioxide at 300 atm and 25°C using an optical pathlength of 10 mm. (B) Increase of absorption of the Fermi resonance bands at 1390 and 1285 cm⁻¹ with increasing CO₂ pressure.

vapour-phase spectra do not currently exist and hence, in the future, libraries of spectra recorded in CO₂ will probably need to be generated.

In cases where detection of the above functional groups is necessary, xenon may be used as an alternative mobile phase. Although xenon is much more expensive than carbon dioxide, it has the advantage of being completely transparent in the IR and background subtraction is less of a problem. However, significant purging with xenon is required to remove the carbon dioxide from the pump and chromatograph completely when changing mobile phases. Spectra measured in xenon also more closely match available vapour-phase library spectra than spectra obtained in carbon dioxide. Xenon is nontoxic, has critical parameters ($T_c = 16.6^\circ\text{C}$, $P_c = 57.6\text{ atm}$) that are similar to carbon dioxide and is compatible with other chromatographic detectors such as the flame ionization detector. Even though only a limited amount of research has been undertaken with xenon as a mobile phase, most reports indicate that it has similar chromatographic properties to carbon dioxide for nonpolar analytes, but is inferior to carbon dioxide for polar analytes.

As far as other fluids are concerned, supercritical nitrous oxide has been shown to be unsuitable for flow cell SFC/FTIR, whereas supercritical sulfur hexafluoride affords transparency solely in the 3000 cm⁻¹ region (i.e. for detection of C-H stretching bands). It has been shown that several chlorofluorocarbons that have moderate critical temperatures and pressures, such as Freon-23 (trifluorochloromethane), have significant regions of transparency and complement carbon dioxide. For example, the O-H stretching region at 3600 cm⁻¹ cannot be monitored in carbon dioxide, but can be monitored in Freon-23. Finally, the addition of polar modifiers is often required to increase the solvent strength of carbon dioxide or to deactivate active sites on stationary phases, especially in packed column SFC. Unfortunately, the addition of a polar modifier such as an alcohol to carbon dioxide reduces the applicability of the online method. Addition of 1% hexanol to CO₂, for example, blocks large regions of the mid-IR spectrum, while addition of 0.2% methanol has been shown to reduce the IR-accessible windows to 3400–2900 cm⁻¹, 2800–2600 cm⁻¹, 2100–1500 cm⁻¹ and 1200–1100 cm⁻¹.

Flow Cell Design Criteria

A number of factors must be considered when using a flow cell interface: choice of chromatographic column (i.e. packed or open tubular), flow cell dimensions, materials of construction of the cell body, windows and seals, the mobile phase and the detection

conditions. A schematic diagram of a high pressure flow cell is shown in **Figure 3**. The major chromatographic requirements of the cell are that it must withstand the high pressures used in SFC (up to 500 atm) and that it has a small volume in relation to the volume of a typical peak eluting from the column to prevent band broadening. To withstand high pressure, most flow cells have been constructed from stainless steel, and ZnS, CaF₂ or ZnSe window materials, have been used with polytetrafluoroethylene (PTFE) or Kel-F seals. To prevent band broadening, the cells must be designed to minimize dead volume in the connections and flow path and the cell volume should not exceed 0.3 SD or about 25% of the volume of a Gaussian peak. However, the peak volume is dependent on the column type. For example, peak volumes in typical 4.6 mm i.d. packed columns are in excess of 40 µL and cell volumes of 10 µL are therefore optimal. For capillary SFC, open tubular columns are typically 50 µm in internal diameter and a typical peak has a width at half height of about 15 s at 150 atm when operated at a flow rate of 1.5 µL min⁻¹. This corresponds to a peak volume of 400 nL and hence the optimal detector volume is in the region of 100 nL. Unfortunately, cells with such small volumes are very difficult to make and are also in conflict with the requirements of the FTIR. Inevitably, a compromise between chromatographic and spectroscopic requirements must be reached.

For maximum IR sensitivity, the dimensions of the flow cell must also be taken into account. According to the Beer–Lambert law, the IR absorbance (A) is dependent on the sample molar extinction coefficient (ϵ), the sample concentration (c) and the cell pathlength (l). Thus, increasing l should improve the signal-to-noise ratio of the spectra obtained. However, l can only be increased so much before absorption by the mobile phase (except with xenon) becomes too intense to allow an adequately low noise level after spectral subtraction. Furthermore, in order to maintain a constant cell volume, the light pipe diameter must decrease as l increases, and this leads to a drop in optical throughput. As the minimum attainable beam diameter is approximately 1 mm using state-of-the-art beam-condensing optics, a cell light pipe diameter less than this must reduce the available energy transmitted through the cell. Consequently, the minimum practical cell diameter is 0.5 mm. Pathlengths of flow cells used in packed column SFC/FTIR have ranged from 5 to 10 mm, while those used with open tubular columns have typically been 1–5 mm to reduce the cell volume as much as possible. Construction details of some flow cells reported in the literature and the experimental conditions under which they were used are summarized in **Table 2**.

Figure 3 Schematic diagram showing the important design aspects of a high pressure flow cell used for SFC/FTIR.

A number of flow cell SFC/FTIR studies have been performed to determine the minimum identification limit (MIL), defined as the quantity of compound required for identification by spectral interpretation, and the minimum detectable quantity (MDQ), defined as the quantity of material which must be injected to yield an IR response three times the noise level. Although these limits are dependent on the strength of the IR absorption of the compound, an MIL of 10 ng methyl palmitate and an MDQ of 2 ng caffeine have been reported using capillary columns and a flow cell with a 5 mm pathlength.

Application

One of the advantages of the flow cell approach is that chromatograms based on total or selected IR absorbance of the organic molecules can be reconstructed using the Gram-Schmidt algorithm. Further FTIR can also be used as a chemically specific detector, by reconstructing absorbance data in a specific wavenumber region. The IR spectra of the peaks contained in the associated data files can be retrieved and manipulated to remove the spectral features of

the mobile phase. Most packed column studies have been performed with CO₂ at constant pressure and temperature. In this condition, the IR spectrum of the mobile phase does not change during the course of the chromatographic run, facilitating subtraction of the background mobile-phase spectrum from the spectrum of each of the analytes and generation of a GSR chromatogram. In capillary SFC, however, the mobile phase is typically programmed from a low to a high pressure and Gram-Schmidt orthogonalization must be used to prevent this baseline rise. This procedure has been developed: vectors containing the information from the rising baseline are added to the basic set and the chromatogram is then recalculated to remove the baseline drift and to enhance the signal intensity. A flow cell SFC-FTIR analysis of a UV-curing coating in **Figure 4** exemplifies these features.

Many other thermally labile and nonvolatile samples have been analysed by flow cell SFC/FTIR, including free fatty acids, sesquiterpene hydrocarbons, carbamate pesticides, double-base propellants, steroids, triglycerides, aromatic plasticizers and aromatic isocyanates.

Mobile-phase Elimination SFC/FTIR

All of the commonly used supercritical fluid mobile phases are gaseous at STP. Thus, analytes can be trapped in some way at the restrictor outlet (connected to the column outlet) as depressurization and evaporation of the mobile phase occur. This is the basis of the mobile-phase elimination approach. Griffith's research group was the first to demonstrate the potential of this methodology in 1986. They realized that this approach had a number of advantages over using a flow cell. Firstly, as most SFC applications were aimed at involatile materials, most of the analytes could be trapped on an IR transparent material at ambient temperature for FTIR analysis. Secondly, as the mobile phase could be easily removed, the complete condensed-phase IR spectrum could be measured without interference from mobile-phase absorbance bands. Thirdly, a large number of scans of the trapped analyte could also be added together to improve the signal-to-noise ratio significantly. Lastly, they recognized that the technique was potentially amenable to mobile phases (and modified mobile phases) that could not be used with flow cells.

Offline Studies

Initial work involved depositing each separated component on a moving glass plate on which a layer of powdered KCl had been laid down from a methanol slurry. A 1 mm i.d. silica packed column and 2% methanol in carbon dioxide was used to separate a mixture of quinones and diffuse reflectance spectra of the separated quinones were measured by moving the substrate into the focused beam from an FTIR spectrometer. Later work by the same group and others showed that it was not necessary to use a pow-

dered substrate and that superior results could be obtained using capillary SFC simply by depositing the eluted compounds on to a zinc selenide or potassium bromide window. The window could then be mounted on the sampling stage of an FTIR microscope and each spot located visually under the microscope. Once located, the transmittance IR spectrum of each spot could be measured by directing the focused FTIR beam through the sample within the microscope.

Important aspects of mobile-phase elimination SFC/FTIR are illustrated in Figure 5. With this approach, the mobile-phase flow from the end of the column is usually split to permit simultaneous detection by another means (for example, using flame ionization or UV absorbance detection) and thus permit identification of the deposition period. When an FID is used, the flow rates of each of the restrictors must be adjusted so that the FID detects the component first. The zinc selenide window can then be moved so that deposition takes place on a fresh area of the window.

Most early depositions were performed offline with the substrate stationary beneath the restrictor. These experiments allowed the shape and dimension of the deposit to be characterized and demonstrated that it was possible to deposit compounds emerging from a capillary SFC column as spots approximately 100 µm in diameter. From a spectroscopic standpoint, minimizing the spot diameter is the key to obtain the maximum FTIR sensitivity since, for a given sample quantity, the average thickness varies inversely with the cross-sectional area. Keeping the spot diameter as small as possible enables the analyte to be deposited as thickly as possible and results in greater IR absorbance according to the Beer-Lambert law.

Figure 4 Flow cell SFC/FTIR analysis of an UV-curing coating. (A) Gram-Schmidt reconstructed chromatogram. (B) Gram-Schmidt reconstructed chromatogram with added basis vector 346 to remove the baseline drift from the increased CO₂ absorbance due to the mobile-phase pressure programming. (C) Selective FTIR detection of carbonyl stretching region of an aromatic ketone (1670–1690 cm⁻¹). (D) IR spectrum of photoinitiator detected in the 1670–1690 cm⁻¹ reconstructed chromatogram. Conditions; 10 m × 50 μm i.d. open tubular column; poly(biphenylmethyl)siloxane stationary phase; 65°C; CO₂; pressure programme from 100 to 250 atm at 2.5 atm min⁻¹ followed by 15 min isobaric hold. (Reproduced with permission from Bartle *et al.*, 1989.)

In practice, deposition characteristics depend on the physical properties of the analyte, the temperature of the SFC restrictor (and the window) and the flow rate of the mobile phase leaving the restrictor. Most analytes that are solids can be successfully trapped on a window at room temperature, even though they may exit the restrictor in liquid form. In SFC, the

restrictor must be heated to 100–250°C to prevent it becoming plugged with analytes as they come out of solution from the depressurizing mobile phase. Analytes that are liquid are often too volatile and do not solidify rapidly enough on a surface at ambient temperature; they may be blown off or spread out over the window surface by the expanding mobile

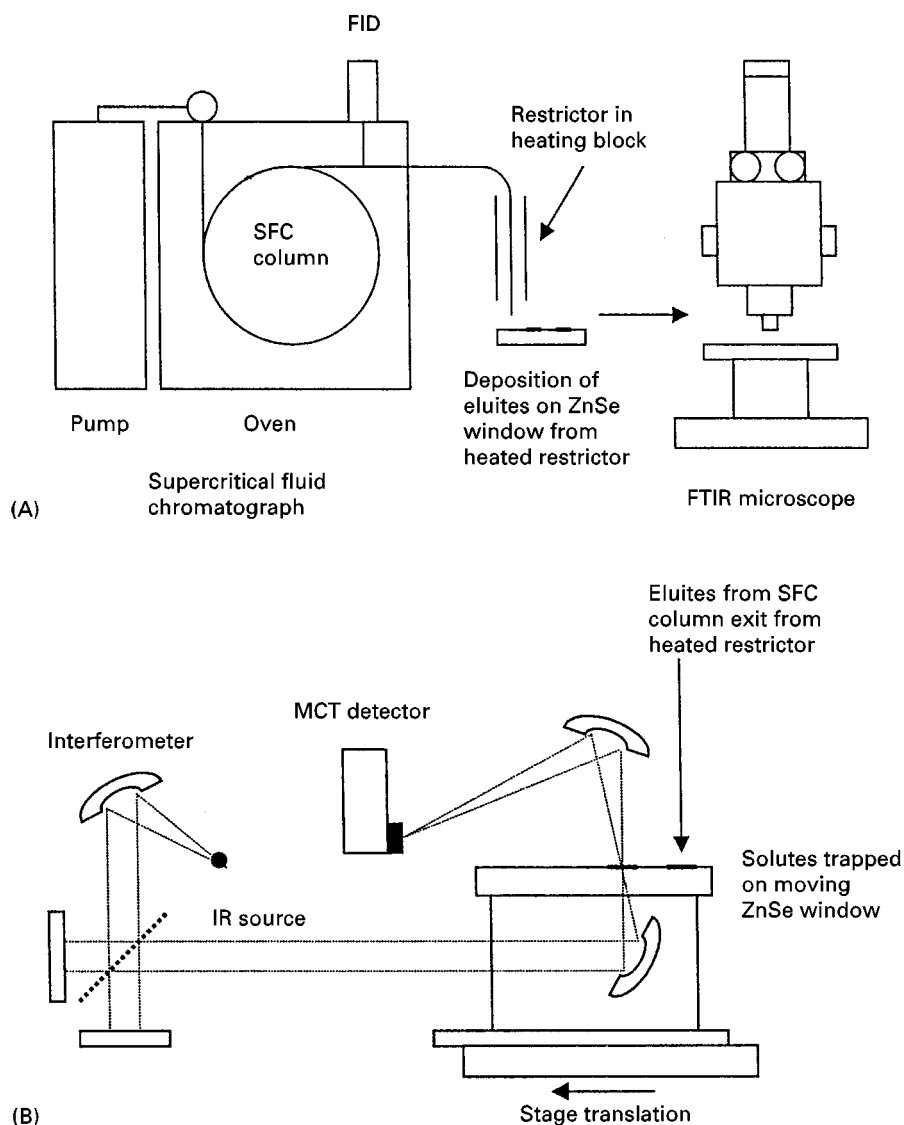

Figure 5 Mobile-phase elimination SFC/FTIR. (A) Offline approach: after deposition on a ZnSe window, the substrate is placed in the focused beam of an FTIR microscope and the spectrum of the eluite is measured with the window stationary. (B) Online approach: after deposition on the moving window, the eluite passes through the focused IR beam.

phase. This was demonstrated by one group who analysed 21 common polymer additives varying in molecular mass from 225 to 1178. Only Topanol OC was unretained on the window, due to its high vapour pressure. The other additives were either deposited as liquids or solids, with spot sizes that ranged from 200 to 300 μm in diameter. By cooling the window, it is possible to capture volatile compounds, but this significantly complicates an otherwise simple interface. High quality IR spectra were typically measured from a 100 ng deposit by adding 1000 scans using a quality IR microscope with an MCT detector. However, it is important to take a suitable background IR spectrum from an area of window where a blank deposit, made during a time when no analytes have eluted, has been

collected. This is because the mobile phase can contain hydrocarbon or other contaminants from the pumping system or column that may be deposited along with the analytes. The IR spectrum of the pure analyte is obtained by subtracting the background IR spectrum from that of the crude analyte.

To date, the interface has been demonstrated by a number of groups, with samples containing phenolic carboxylic acids, steroids, polycyclic aromatic hydrocarbons, indoles, quinones and barbiturates. Most measurements have employed capillary columns for the separation. This is because the commonly used 50–100 μm i.d. open tubular columns operate at very low linear velocities and the gaseous flow rates produced by the expanding mobile phase

are only in the region of $2\text{--}5\text{ mL min}^{-1}$. Because of this, application of the methodology to packed column separations using carbon dioxide and modified carbon dioxide has been questioned. It is indeed difficult to deposit analytes using conventional 4.6 mm i.d. packed columns, because the gaseous flow rates are simply too high ($\sim 500\text{--}1000\text{ mL min}^{-1}$). However, reducing the diameter of the packed column to 1 mm i.d. reduces the volume flow rate by a factor of $(4.6)^2$, or 20 times, and allows successful analyte deposition. This was demonstrated for the analysis of sulfanilamides using a 1 mm i.d. Deltabond-CN packed column with 0.1% water in carbon dioxide as the mobile phase. It was possible to obtain high quality IR spectra from $\sim 120\text{ ng}$ sulfisoxazole.

Online Studies

The logical development of the offline work discussed above has been the commercialization of on-line mobile-phase elimination interfaces, in which deposition occurs on a moving window that then passes through the infrared beam. The Bio-Rad Tracer interface (originally designed for GC/FTIR) was adapted for use with SFC: a $50\text{ }\mu\text{m i.d.}$ fused silica transfer line was used with an integral restrictor

fabricated at the end of the tube. The end of the restrictor was placed $75\text{ }\mu\text{m}$ from the ZnSe window ($60 \times 30\text{ mm}$) and heated to 100°C by a cartridge heater. The ZnSe window was cooled to -10°C with a methanol-dry ice mixture to trap compounds efficiently without condensing the mobile-phase. The speed of translating the deposition window was selected to maintain an appropriate compromise between chromatographic resolution and spectroscopic sensitivity. The best compromise was obtained when the distance moved by the window during the time equal to the full width at half height of the narrowest peak in the chromatogram was equal to the diameter of the spot deposited on the stationary window. For most of the SFC work, the window was moved at a rate of $100\text{ }\mu\text{m min}^{-1}$. In order to remove the expanded mobile phase, 0.1 mTorr pressure was maintained in the interface using a 170 L s^{-1} turbomolecular pump. This pumping speed was fast enough that virtually no absorption due to CO_2 was observed at gaseous mobile-phase flow rates less than 5 mL min^{-1} at STP.

The lowest MIL reported to date for caffeine, using online direct deposition SFC/FTIR, is 600 pg . This is significantly lower than can be achieved using a flow

Figure 6 IR spectra measured from (A) 3 ng , (B) 600 pg and (C) 300 pg caffeine during online mobile-phase elimination SFC/FTIR. (Reproduced with permission from Norton and Griffiths, 1995.)

cell interface. The IR spectra measured from 3 ng, 600 pg and 300 pg caffeine are shown in **Figure 6**. The interface has been further demonstrated for on-line measurement of Gram-Schmidt and functional group reconstructed chromatograms of cholinesterase inhibitor pesticides (**Figure 7**) and polycyclic aromatic hydrocarbons using carbon dioxide and for triazine herbicides using carbon dioxide modified with 2% methanol. Clearly, the possibility of using modified mobile phases is one of the great advantages of the mobile-phase elimination approach.

Future Developments

Since the introduction of the first commercially available SFC system in the early 1980s, hyphenated flow cell and mobile-phase elimination interfaces for SFC/FTIR have attained a high level of sophistication. Although the flow cell approach has a number of advantages, including mechanical simplicity and interfacing with other detectors, mobile-phase elimina-

tion interfaces offer greater sensitivity, the potential of using strongly IR-absorbing mobile phases (including modified mobile phases) and enables library-searchable condensed-phase spectra to be measured. Therefore it is reasonable to expect continued evolutionary development of the latter approach. It is also likely that improvements to the instrumentation will be application-oriented. As solutions to difficult analytical problems are sought, it can be expected that SFC/FTIR will be investigated with new columns such as micro-packed columns (250–300 μm i.d capillaries packed with 2–5 μm HPLC packing materials) and new mobile phases such as the fluorocarbons.

Definition

Above the critical temperature, the vapour and liquid of a substance have the same density and the fluid cannot be liquefied by increasing the pressure; the supercritical fluid has density and solvating power approaching that of a liquid, viscosity similar to that of a gas, and diffusivity intermediate between those of a gas and a liquid. A typical phase diagram is shown in **Figure 1**. It follows that supercritical fluids have

Figure 1 Typical phase diagram of a single substance. (Reproduced with permission from Clifford T(1998) *Fundamentals of Supercritical Fluids*. Oxford: OUP.)

properties which make their use as chromatographic mobile phases very favourable. Thus, gas chromatography (GC) produces narrow peaks and high resolution, but cannot be used for involatile or thermally labile compounds since analytes must be in the vapour phase. High performance liquid chromatography (HPLC) is extensively applied to involatile compounds, but has limited resolution because the high viscosity of the mobile phase limits column length, and the low diffusivity slows the exchange of analyte molecules between liquid streams of different velocity. Supercritical fluid chromatography (SFC) addresses these limitations because of increased solubility (which varies with density and hence applied pressure) for involatile compounds in comparison with GC, and lower viscosity and higher diffusivity in comparison with HPLC.

Both capillary and packed columns are used in SFC, and many of the detectors of both GC and HPLC may be employed. Coupling to spectroscopic detectors has proved fruitful. SFC has established a number of niche areas: it extends the range of GC, it can replace many normal phase HPLC methods and it has many advantages over size-exclusion chromatography.

History

Supercritical fluids have been known (**Table 1**) since Baron Cagniard de la Tour observed in 1822 that, above a certain temperature, a liquid can be converted to a gas without the appearance of a meniscus. In 1869, Andrews fully characterized the critical point in terms of critical temperature T_c and critical

pressure P_c . Hannay and Hogarth observed in 1879 that metal halides are soluble in ethanol above the critical point, and as early as 1897 Vuillard reviewed solubility in supercritical fluids. Isolated examples of the use of near-critical solvents for separation appeared between 1930 and 1960; more extensive applications, especially to natural products with the pharmacologically acceptable carbon dioxide have since appeared, based on extensive studies of solubility in supercritical solvents and on the properties of solutions. In parallel with SFC, analytical supercritical fluid extraction (SFE) has been extensively developed as a sample preparation technique.

The original idea for SFC was suggested by Lovelock at an international meeting in 1958, before Klesper, Corwin and Turner separated involatile porphyrins in 1962 using supercritical chlorofluorocarbons at pressures up to 136 bar as mobile phase. In 1966, Sie and Rijnders developed both adsorption and partition chromatography using carbon dioxide, *n*-pentane and isopropanol at temperatures up to 245°C and pressures up to 80 bar.

The advantages of carbon dioxide as a mobile phase were quickly realised: it is an inexpensive material with good solvent properties, convenient T_c and P_c , non-combustible, easily delivered by pumping the liquid, and available in high purity. Although other compounds have since been employed as mobile phases (e.g. N_2O , SF_6 , NH_3 , *n*-butane and *n*-pentane,

xenon, and various fluorocarbons and chlorofluorocarbons), CO_2 has remained the most popular and widely used. Because of the variation of solubility with density and hence pressure, Rijnders suggested in 1967 that pressure programming in SFC should have a similar effect to temperature programming in GC.

In 1970, Jentoft and Gouw constructed a versatile high-resolution SFC chromatograph with a pressure-programming facility for packed columns up to 4-m long and *n*-pentane-methanol mobile phase for temperatures up to 215°C and pressures up to 650 bar; detection was by UV absorption. Styrene oligomers up to $n = 32$ could be analysed with this system. The affinities between GC with a dense gas as mobile phase and SFC were discussed and developed by Giddings between 1966 and 1969.

Novotny pointed out in 1971 the serious limitations in SFC of the pressure gradient generated by the column packing, and realized that SFC should be possible on capillary columns with a much smaller pressure drop. In 1981, Novotny and Lee demonstrated capillary column SFC equipment. Commercial equipment for packed column SFC became available in 1982, and for capillary SFC in 1986.

The 1980–90 period was one of rapid growth in the theory, instrumentation and applications of SFC. A multi-authored text edited by Lee and Markides appeared in 1990 summarizing the state of the art, and remains authoritative. Two series of international conferences on SFC and SFE, one based in USA and the other in Europe began in 1988 and continue.

Instrumentation

Figure 2 illustrates the instrumentation for SFC. The mobile phase is pumped as a liquid and the pressurized fluid passes, via an injection valve, into the column maintained in an oven at a temperature above T_c , and then to a detector. A pressure restrictor to maintain supercritical conditions is located either after the detector or at the end of the column.

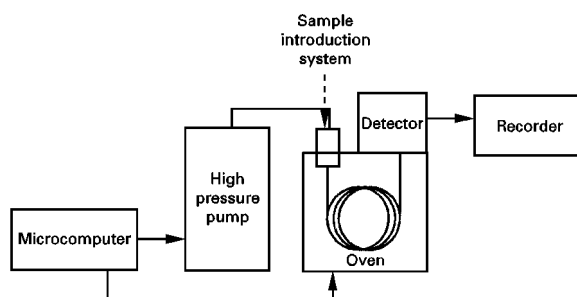

**Figure 2** Schematic diagram of an SFC instrument.

Table 2 Columns in SFC

<i>Column</i>	<i>Internal diameter (mm)</i>	<i>Advantages</i>	<i>Disadvantages</i>
Conventional	2.0–4.6	High capacity	Low overall efficiency
Microbore	1–2	Rapid analysis	Highly activity
Packed capillary	0.2–0.8	Highly selective	
Open tubular	0.05–0.1	Low capacity, high resolution inactive	Long analysis times Selectivity only conferred by stationary phase

Conventional HPLC pumps with cooled heads were used from the start for SFC in packed columns. Syringe pumps were initially used in capillary SFC because of their pulseless operation. Small column diameters necessary in capillary SFC make the method of sample introduction important; small volumes and rapid injection are achieved by a pneumatically operated loop valve with electronic timing.

Columns

Although a full range of columns can be used in SFC, the technique is most usually divided into two categories based on column type, with advantages and disadvantages outlined in **Table 2**. Packed columns for SFC have reflected developments in HPLC: (a) 'conventional' packed columns (up to 4.6 mm i.d.); (b) microbore columns; and (c) packed capillaries with smaller i.d. Most of the work has been carried out on 4.6-mm columns, with 3–10 μm particle size packing materials – usually bonded-silica particles (**Table 3**). It was realized early that the unreacted silanol groups on silica particles which have little activity in reversed-phase HPLC led to peak tailing because of the low polarity of the mobile phase. Such effects led to the almost exclusive addition of organic modifiers (alcohols, ethers, etc.) to the carbon dioxide mobile phase in packed column SFC. These modifiers can influence selectivity and increase the solubility of analytes. A number of specially end-capped silica packings were developed, along with polymer-based

packings, but most of these have had limited use. The low-pressure drop across packed columns has led to the coupling together of columns, with consequent improvement in selectivity and efficiency.

Capillary SFC was only made possible by the development from 1979 onwards of fused silica capillary columns for GC. Because of the slower diffusion of analyte in supercritical fluids, open tubular columns for SFC must have internal diameters less than 100 μm to achieve resolution comparable to that on 200 μm i.d. columns for GC. Lee's group undertook an extensive series of developments of columns for both GC and SFC between 1980 and 1990, basing stationary phase structures on a polysiloxane polymer backbone with pendant groups 'designed' for particular applications. As well as the more usual methyl- and phenyl-containing phases (**Table 3**), polymers with biphenyl, cyanopropyl and ethylene glycol, etc., groups were synthesized; more exotic phases had bonded liquid crystal or chiral groupings. Capillary columns for SFC are highly inert and are usually operated with CO_2 alone as mobile phase.

Detectors

SFC can be carried out with the widest range of detectors of any chromatographic technique: detectors from gas and liquid chromatography are employed, and SFC can be coupled to a number of information-rich spectroscopic detectors (**Table 4**). SFC detection can be carried out in the gas phase after decompression, or in both supercritical and liquid phases. The flame ionization detector (FID) is the most commonly used if unmodified CO_2 is the mobile phase, as is the case for capillary columns, whereas the UV/visible detector is most often used if a mobile phase contains a modifier, e.g. in packed column work. Some limited use has been made of the FID with CO_2 modified by water, formic acid or formamide which give no, or a very small, FID signal.

From 1981 the range of detectors for SFC showed a rapid expansion. The thermionic, electron-capture, photoionization and chemiluminescence detectors from GC, and the fluorimetric and light-scattering

Table 3 Bonded stationary phases in SFC

<i>Packed SFC</i>	<i>Capillary SFC</i>

Table 4 Detectors in SFC

Type	Established	Developmental
GC type	Flame ionization	Chemiluminescence
	Thermionic	Photoionization
	Flame photometric	Ion mobility
	Electron capture	Element-specific plasma
LC type	UV absorption	Fluorescence
		Light scattering
		Electrochemical
Coupled	Diode array UV	Nuclear magnetic resonance
	Fourier transform IR	Inductively coupled plasma
	Mass spectrometric	spectrometry

detectors from HPLC were all demonstrated in SFC. Element-specific plasma emission detectors were demonstrated in SFC from 1987, and since 1990 electrochemical detection has been explored; if the electrodes are sufficiently small, oxidative and reductive detection is possible in CO₂ containing only small concentrations of water or organic modifier.

The detector providing the most structural information in chromatography is the mass spectrometer (MS); a packed-column SFC–MS interface was first reported in 1978, and a practical SFC interface was developed in 1982 for capillary SFC–MS where the low flow rates permit direct introduction into the ion source. A practical packed-column SFC–MS interface was developed in 1987 to cope with the higher flow rates. SFC with both electron impact and chemical ionization has been demonstrated. The interfacing of capillary SFC to Fourier-transform infrared spectroscopy (FTIR) was achieved as early as 1983. Both solvent-elimination (evaporation of CO₂ to deposit separated compounds on a solid substrate or IR transparent plate) and online direct recording of FTIR spectra in a flow cell with IR transparent optics were developed between 1983 and 1990. A major problem with the latter approach is strong IR absorption by CO₂; alternative supercritical mobile phases, especially xenon, have therefore been employed but xenon is vastly more expensive than CO₂. Recently, NMR detection has been explored in SFC.

Applications

After early exponential growth up to 1990, SFC has consolidated to maintain applications complementing GC and HPLC, mainly in the analysis of lipophilic compounds. **Figure 3** illustrates the perceived application areas. Particularly noteworthy have been applications to: fossil fuels and hydro-

Non-volatile analytes
Thermally unstable analytes } → Extends GC range towards higher molecular weight

Non-detectable analytes
(i.e. lacking UV chromophore) } → Extends normal phase HPLC and SFC (e.g. for oligomers)

Complex analytes

Chiral analytes

Figure 3 Application areas of SFC.

carbons (where simulated distillation at low-temperature and group-type separations have been particularly important); agrochemicals; explosives; drugs and pharmaceuticals (especially those normally analysed by normal-phase HPLC); lipids and other nonpolar biomolecules; industrial chemicals (especially surfactants and polymer additives); and metal chelates and organometallic compounds. A current growth area is in chiral separation, where the rapid speed of analysis in SFC also permits preparative separations. Current developments are aimed at eliminating the distinction between gaseous and supercritical fluid mobile phases.

Introduction

Supercritical fluid chromatography (SFC) is an instrumental technique in which a small volume of a sample is entrained in a solvating mobile phase, held near its critical point, and is swept through a stationary bed of particles, or a tube coated with a liquid film. The components of the mixture are separated from each other through differential solvation by the mobile phase, and retention by the stationary phase. SFC can be viewed as a transition technique between GC and HPLC.

A fluid is 'supercritical' when it is raised above its characteristic 'critical point' (a critical temperature, T_c , and a critical pressure, P_c). Most fluids used as SFC mobile phases are gases at room temperature and pressure but all are easily liquefied by raising the pressure. In a supercritical fluid, the molecules are forced close together by an externally applied pressure. Some but not all supercritical fluids act as a solvent. Changing the density of such fluids changes their solvent strength.

Packed vs. capillary columns There are two SFC techniques, using either open tubular (capillary), or packed columns, each of which exploits a different aspect of the technology. Although in 1958 Lovelock originally proposed SFC as a capillary technique, for its first 20+ years SFC was exclusively performed with packed columns. The first commercial instrumentation for packed-column SFC was introduced in 1982 as a modification kit for a HPLC. Capillary SFC was not viable until the late 1970s when stationary phases were first bonded to the surface of the column. Earlier stationary phases were washed out of the column by the SFC mobile phase. In 1981, the groups of Lee at Brigham Young University and Novotny at Indiana University, combined bonded stationary phases with SFC and published the first realistic capillary (open tubular column) SFC chromatograms.

Subsequently, a rather unfortunate controversy raged for some years as to whether capillary or packed columns were 'better'. However, the two techniques are sufficiently different that almost any attempt to compare them will show one or the other unfavourably.

Open tubular or capillary SFC (CSFC) is almost always performed using pressure programming of

pure carbon dioxide as the mobile phase. CSFC can be thought of as an extension of gas chromatography (GC) to higher molecular masses, since the solvation energy of the fluids can replace thermal energy. Elution temperatures can be 200°C or more lower than in GC (i.e. carbon dioxide at 150°C vs. GC with hydrogen at 400°C). The column temperature is almost always maintained at >50°C above the critical temperature.

The fluid solvent strength can be changed in a predictable manner by programming the fluid density (usually pressure, sometimes temperature, rarely both). Carbon dioxide is compatible with the flame ionization detector (FID). The most common uses of CSFC are for the separation of light polymers, surfactants and other homologous series.

Carbon dioxide has a solvent strength similar to hexane or a fluorocarbon. Relatively nonpolar solutes such as hydrocarbons are miscible with carbon dioxide. Polar solutes such as sugars or amino acids are virtually insoluble in carbon dioxide.

Packed columns are, inherently, 10 to 100 times more retentive than capillary columns, due to their higher surface area to void volume ratio. This makes it more difficult to elute molecules from packed columns using pure carbon dioxide. On the other hand, the low polarity of carbon dioxide is incompatible with the solvation of polar molecules.

The most widely used approach to extending SFC to more polar solutes has involved the use of packed columns with binary or ternary mobile phases. Binary fluids consist of a normal liquid such as acetonitrile or methanol mixed with carbon dioxide. Ternary mobile phases consist of a fraction of a percent to several percent of a third, even more polar component, such as trifluoroacetic acid or isobutylamine, added to the liquid modifier. The use of modifiers was pioneered by Jentoff and Gouw in 1969. The use of additives was pioneered by Berger *et al.* starting in 1988.

Once a modifier is added to the mobile phase, the composition of the fluid tends to dominate over its density in determining solvent strength. Pressure programming becomes a secondary control variable. The enhanced solvent strength of modified fluids tends to be less compatible with the inherent low retentivity of capillary columns.

Packed-column SFC can be thought of as an extension of HPLC, using modifier concentration gradients of binary or ternary mixtures near (within 50°C above or below!) their critical temperature. Packed-column SFC is a form of normal-phase chromatography, complementing reversed-phase HPLC, but with

superior speed, and efficiency. The low temperatures used make packed-column SFC ideal for separation of moderately polar, thermally labile molecules. The primary detection scheme with packed columns is UV absorption.

Packed-column and capillary SFC are two different techniques sharing part of a name. As with GC and HPLC there is clearly an overlap between the two. Packed columns are sometimes used with pure carbon dioxide, pressure programming and FID detection, to perform some of the applications more commonly performed by capillary SFC. Some relatively polar solutes are soluble enough in carbon dioxide to allow elution with capillaries and pure carbon dioxide.

Unified chromatography A further problem in defining these techniques is the fact that there are no real borders between GC, SFC and HPLC. One can start an experiment, above the mobile phase critical temperature (T_c) (i.e. as GC), then raise the pressure above the critical pressure (P_c) (to SFC), then drop the temperature below T_c (to LC). In the process the name of the technique changes from GC, to SFC, to HPLC, but there is never more than one phase present, and there is never a phase transition. Changes in solute retention, viscosity, diffusion coefficients, etc., are smooth and continuous, even when the definition of the fluid changes. In packed-column SFC, modifier concentration can be programmed from 0 to 100%. At some intermediate (but not obvious) concentration, the definition of the technique changes from SFC to HPLC. The characteristics of interest in SFC are summarized in Table 1. SFC has additional special advantages when scaled up for preparative use.

There has been some effort to promote SFC as a form of unified chromatography. SFC instrumentation can typically also perform HPLC, and at least

Figure 1 A summary of solute families which have been separated by SFC.

some GC, whereas instrumentation for the other techniques cannot perform much SFC.

Solutes Typical samples separated by packed column SFC consist of low to moderate polarity organic solutes with relative molecular masses $\leq 10\,000$ Da. As a 'rule of thumb', solutes that can be dissolved in methanol or a less polar solvent are good candidates for SFC. On the other hand, solutes requiring water or buffered or pH adjusted water environments are a poor choice. Solute families which have been separated by SFC are summarized in Figure 1. Low polarity solutes are to the left, higher polarity solutes to the right. At the bottom of the figure, there is an attempt to relate the nature of the mobile phase needed to elute the various solute families.

Fluid Characteristics

Other pure fluids used A few common fluids are listed in Table 2. However, carbon dioxide remains the fluid of choice for SFC in spite of its inherently low polarity. It has a modest critical pressure and temperature, is inexpensive, readily available, safe, and compatible with the FID.

Some early work used supercritical pentane mixed with alcohols at $>235^\circ\text{C}$. The flammability of such mixtures means that today they are rarely used. Nitrous oxide has characteristics similar to carbon dioxide but is also an extreme oxidizer. It should not be mixed with fuels such as organic modifiers. Fluids like ammonia are also obviously potentially dangerous and corrosive.

Table 1 Characteristics of interest in SFC

A compressible fluid that acts as a solvent
Solvent strength changes with a physical parameter (pressure)
Very wide range of solvent strength using one binary pair of solvents
Low viscosity
long, high efficiency columns (i.e. $>2\text{ m}$ with $5\text{ }\mu\text{m}$ particles)
low pressure drop at high flow with smaller particles
Higher speed than HPLC – higher diffusion coefficients
3–10 \times higher throughput
much faster re-equilibration
rapid method development
Compatibility with GC detectors, like the FID, ECD, NPD
Transparent in the UV
Complementary selectivity to reversed-phase HPLC
Low cost, environmentally friendly solvents, easily removed

Table 2 Critical parameters of some of the pure fluids used for SFC

	<i>Critical temp. (°C)</i>	<i>Critical pressure (atm)</i>
Carbon dioxide	31.1	72.8
Nitrous oxide	36.4	71.5
Sulfur hexafluoride	45.5	37.0
Trifluoromethane	25.9	47.7
Ammonia	132.3	111.3
<i>n</i> -Pentane	196.6	41.7
Methanol	239.4	79.9
Water	374.1	217.6

Some chlorofluorocarbons have interesting properties but have been banned due to their ozone depletion potential in the environment. Several replacement fluorocarbons, especially F-134a, have recently shown potential for extending the polarity range available with a pure fluid. Sulfur hexafluoride has been used as a mobile phase, particularly in the study of hydrocarbons, but is also an ozone depleter. Its main utility is its compatibility with the FID, although a combustion product is hydrofluoric acid. Fluorocarbons exhibit the same problem.

Density At constant temperature, the log of retention in SFC is a nearly linear function of density. Changing the density of the mobile phase can result in a change in retention of 3 or 4 orders of magnitude. Using carbon dioxide as the mobile phase, the usable density range is from gas-like densities (i.e. 0.002 g cm^{-3}) to a density similar to water ($>0.95 \text{ g cm}^{-3}$). The typical pressure range is 60 to 400 or 600 bar. The typical temperature range is from 40 to 250°C , but temperatures above 150°C are seldom used.

Modifiers None of the pure fluids used in SFC are polar, and polar solutes are typically insoluble in them. Solvent polarity can be increased by adding polar modifiers, such as alcohols to the nonpolar main fluid. The increase in solvent strength is nonlinear. The addition of 2% methanol to carbon dioxide yields a fluid with the polarity one might expect from 10% methanol. This enhanced solvent strength is due to a phenomenon, sometimes called clustering, where the polar modifier molecules tend to cluster together, creating small pockets of greater than expected polarity. Polar solutes tend to be solvated within, and by, these clusters. The clusters are too small to be considered micelles or a different phase. Individual modifier molecules freely exchange in and out of the clusters.

Once a polar organic modifier is added, the composition of the mobile phase dominates over its density in determining the chromatographic retention of a solute. Gradient elution through composition programming becomes the primary means of retention control. Pressure control becomes a secondary variable. The densities of most binary fluids are unknown, and equations of state of binary pairs are inaccurate, making density programming problematic.

In SFC the composition of the mobile phase can be programmed from 0 to 100% modifier. Methanol is among the most polar liquids that is completely miscible with carbon dioxide. On Snyder's solvent strength scale widely used in HPLC, hexane has a strength of 0, water has a strength of 10.4, and methanol has a strength of 5.1. Thus, the solvent strength can be programmed over approximately half the solvent strength scale available in chromatography, using a single binary pair of common solvents. Changing the identity of the modifier can change selectivity.

Additives The polarity range amenable to SFC has been extended significantly by the use of ternary mobile phases consisting of carbon dioxide, methanol, and a low concentration of a much more polar substance called an additive. Without an additive most primary aliphatic amines and most polyfunctional acids will not elute or elute with severe tailing. The inclusion of additives often results in elution of symmetrical peaks with high efficiency. Additives appear to function through multiple mechanisms, although much more work is still required to understand their role better. The most effective additives usually contain stronger members of the same functional group. For example, trifluoroacetic acid is usually effective in improving the elution of other acids, while isopropylamine is effective in eluting amines. Ion pairing, where an acid is added to a base or a base to an acid is seldom effective.

Viscosity One of the more interesting aspects of the fluids used as mobile phases in SFC is their low viscosity, which is more gas-like than liquid-like, even at high densities. For example, the viscosity of carbon dioxide is typically an order of magnitude lower than water. At 20°C and 200 bar the density of liquid carbon dioxide is over 0.9 g cm^{-3} , yet its viscosity is 10.3×10^{-4} poise. At 20°C and atmospheric pressure, the viscosity of water is 100.2×10^{-4} poise. Low viscosity clearly produces the practical advantage of minimizing pressure drops across columns. Very long, high efficiency columns can be used. Compared to HPLC, an SFC column can be run at 2.5 times the flow with 0.25 times the pressure drop. As

the modifier concentration in binary fluids increases, the viscosity of the fluid approaches that of normal liquids.

Diffusion coefficients and speed of analysis Any one column can theoretically be used for GC, SFC or HPLC. Columns can be characterized by the number of 'plates' they exhibit. A column generating many plates can resolve more complex mixtures and is said to have higher efficiency than one generating only a few plates. Another way of describing column efficiency is plate height, H , which is the distance along the column equivalent to one plate. The total number of plates, N , a column exhibits corresponds to the total length, L , divided by the plate height, H ($N = L/H$).

The van Deemter equation, which can be written as: $H = A + 2[D/u] + k[u/D]$, relates the plate height, H , to the solute binary diffusion coefficient in the mobile phase, D , and the linear velocity of the mobile phase through the column, u . Plots of H vs. u show that the minimum value of H (yielding maximum resolving power for a given column) is the same, regardless of the technique, but the optimum speed for pushing the mobile phase through the column depends on the diffusion coefficient of the solute in the mobile phase.

In GC, values for D are of the order of 0.1 to $1 \text{ cm}^2 \text{ s}^{-1}$. In HPLC, a typical D is of the order of $10^{-5} \text{ cm}^2 \text{ s}^{-1}$. Diffusion coefficients in SFC range from 0.01 down to $10^{-4} \text{ cm}^2 \text{ s}^{-1}$. As usually practised, SFC is at least 100 times slower than GC but up to 10 times faster than HPLC. As the modifier concentration is increased in binary fluids, diffusion coefficients approach those in HPLC.

Instrumentation

By the early 1970s, it was generally recognized that HPLC was simpler, easier and more generally applicable than SFC. As an indication of how widespread that conclusion was, no commercial equipment for SFC existed until around 1982. By 1985, commercial SFCs for use with capillary columns appeared. More recently, several companies have introduced instrumentation specifically designed for packed-column SFC or for both packed- and capillary-column SFC.

Instrumentation for Capillary SFC

A schematic representation of the instrumentation required for capillary SFC is shown in Figure 2. In capillary SFC, the main method for changing retention is to change the mobile phase density. Pressure is the primary control variable, temperature is a secondary control variable. The pump is used as a pressure

Figure 2 Schematic representation of instrumentation required for capillary SFC.

source. Pressure or density programming is used much like temperature programming is used in GC. Both negative and positive temperature programmes have been used.

Columns The most commonly used capillary columns are 50 or $100 \mu\text{m}$ i.d. and 10 m long, they are made of fused silica tubing. A wide range of stationary phases are available, including many that are more polar than those used in GC. The optimum mobile phase flow rate is inversely related to the density of the fluid and is of the order of 0.1 to 1 cm s^{-1} .

Pumps The most common pumping systems for CSFC are built around 100 to 250 cm^3 syringe pumps, capable of generating pressures of 400 to 600 atmospheres. Syringe pumps are ideal for controlling pressure. When combined with a computer, the pressure of the pump and the temperature of a column oven can be used to calculate the pressure profile required to generate density ramps.

Syringe pumps can be difficult to fill with a single phase. Any gas present must be re-liquefied before the pump can deliver high pressures. Liquefying the gas can require most of the piston displacement. It has become a common practice to purchase carbon dioxide in cylinders with a helium headspace, raising the pressure to a point where the carbon dioxide is always a liquid. In addition, the syringe is chilled using a recirculating bath, further helping to liquefy the fluid.

Capillary columns are seldom used with mixed mobile phases, due partly to the inherent low retentivity of the columns and partly to instrumental difficulties using syringe pumps to generate composition gradients. Syringe pumps cannot control both pressure and (relative) flow simultaneously. When modified fluids are used with syringe pumps they are usually either premixed in a cylinder or made by adding a known volume of a liquid modifier to the syringe then filling with the main fluid (no composition gradients).

Neither binary fluids premixed in a cylinder nor helium headspace should be used. As such cylinders are used up, the concentration of modifier and/or helium in the carbon dioxide changes, changing the fluid solvent strength. Retention can change by a factor of 2 between a nearly full and a nearly empty cylinder.

Flow control reciprocating pumps can be used as a pressure source, when used with a back-pressure regulator (BPR), as shown in **Figure 3**. The pump(s) deliver a large (i.e. 2 mL min^{-1}) flow of mobile phase to a vessel located upstream of the BPR. A tee allows some of the flow to be drawn off to the injection valve and column. The BPR can be programmed to change the pressure in the vessel. The fluid leaving the BPR can be vented or recycled to the inlet of the pump.

Injection High pressure injection valves similar to those for HPLC are used to introduce liquid samples into the chromatograph. Unfortunately, an ideal injection volume for a $50 \mu\text{m}$ i.d. column should be $<4 \text{ nL}$ (a plug 2 mm , 40 column diameters long, in the column). Since there are no fixed loop injectors with such small volumes, split injection schemes are most often used. Timed split injectors move the rotor of a 0.060 to $0.2 \mu\text{L}$ internal loop valve back and forth fast enough so that only part of the loop volume is pushed on to the column.

Traditional flow splitters use a 'tee' mounted just downstream of the valve. A piece of larger inner diameter (i.e. 0.5 mm) stainless steel (s.s.) tubing connects the valve to the tee. The column is usually

pushed through the tee and up inside the s.s. tube until it touches the valve rotor, then it is pulled back $1\text{--}2 \text{ mm}$. A larger volume (i.e. $0.1\text{--}0.5 \mu\text{L}$) sample loop is switched in-line and swept with 10 to 100 times the column flow. Most of this flow and sample is vented through a restrictor mounted in the side arm of the tee.

Split injections tend to give poor reproducibility, due mostly to the difficulty in mixing a liquid sample with a much lower density supercritical fluid a very short time before the split. Many alternate injection schemes have been developed to allow larger injections and/or better reproducibility.

Retention gaps (an empty length of deactivated capillary tubing) allow much larger injections with better reproducibility. By carefully controlling the initial temperature and pressure, the sample can be distributed as an annular film along a retention gap, with the mobile phase passing through the film, along the axis of the tube. Since the fluid rapidly becomes saturated with the sample solvent, only the solvent at the head of the gap is vaporized or dissolved. The film of solvent progressively becomes shorter, while the sample becomes concentrated in the remaining film. When all the solvent is removed, the sample components are concentrated in a narrow band on the retention gap, and are then differentially eluted with a density programme.

Ovens The temperature of the fluid is important in determining its density and thus the retention of solutes. However, temperature has an effect on retention independent of density. To programme an increase in density using only the temperature, the user would start at a high temperature and decrease temperature over time.

In CSFC, the temperature is almost always held at least 50°C higher than the critical temperature. With carbon dioxide as the mobile phase ($T_c \approx 31^\circ\text{C}$) the most common temperatures used are between 100 and 150°C . Since CSFC most often uses GC detectors, along with these higher temperatures, large GC-like ovens are used.

Restrictors With CSFC, the flow of the mobile phase through the column is only indirectly controlled using fixed restrictors mounted on the outlet of the column. Increasing the column head pressure causes large changes in flow (and efficiency) in the column. There are no devices with small enough inner dimensions to allow the pump to act as a flow source (controlling linear velocity), while independently controlling the outlet pressure, without destroying the separation. There have been numerous schemes to minimize changes in flow through restrictors caused by pressure

Figure 3 Flow control reciprocating pump used as a pressure source when used with a back-pressure regulator.

Figure 4 Two types of restrictors in common use.

changes, but they are all relatively complicated or expensive and have not been widely adopted.

There are two types of restrictor in common use: integral and frit, as shown in **Figure 4**. Integral restrictors are 1–2 μm diameter, <25 μm long pinholes formed at the end of a piece of fused silica tubing. They were originally formed on the end of the column and were integral to it. Today, they are usually made of a separate piece of tubing and attached to the column using a butt connector.

Frit restrictors consist of a porous plug of material formed inside a piece of 50 μm i.d. fused silica tubing. The plug is usually 1–2 cm long. Frits have many small tortuous paths.

Integral restrictors have better flow vs. pressure characteristics but are much easier to plug than frit restrictors. However, since the pressure drops along the full length of the frit, the density at its outlet can

be low so that heavier solutes may drop out of solution and are lost inside the frit. For high molecular mass materials, the only choice is an integral restrictor. All restrictors plug over time, changing flow characteristics through the column. Restrictor performance is the weakest link in SFC instrumentation.

Detection One of the greatest advantages of CSFC with carbon dioxide is its compatibility with the flame ionization detector (FID). The FID is universal and exhibits uniform response factors for hydrocarbons, while allowing a change in solvent strength through pressure or density programming. The restrictor at the end of the column is mounted directly in the base of the detector. The fluid expands to a gas in the flame.

Although both UV and fluorescence detectors have been used in CSFC, the light pathlength is typically the column diameter (i.e. 50 μm). Standard HPLC flow cells have pathlengths 200 times longer. Both detection limits and dynamic range are, thus, compromised.

Instrumentation for Packed-column SFC

The instrumentation used for packed-column SFC can be somewhat more complex than capillary SFC as shown in **Figure 5**. Most of the hardware, including injection valves, columns and some detectors, are the same or similar to that used for HPLC. Binary and ternary fluids are the norm, although low polarity solutes can often be eluted with pure carbon dioxide. Changing the mobile phase composition is the most effective way to change solute retention. Composition gradient elution is most common, although pressure, temperature and even flow can also be programmed. Selectivity is often most easily changed by changing the temperature. Pressure is a secondary control variable.

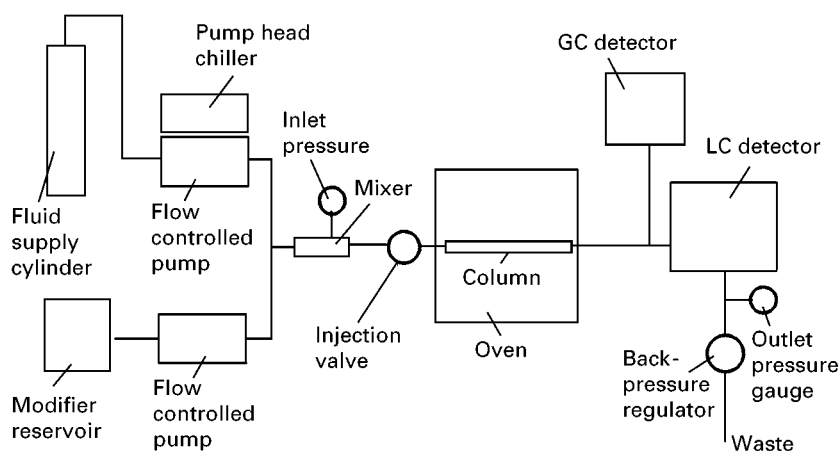

Figure 5 Instrumentation for packed-column SFC.

Columns Standard HPLC columns are used for packed-column SFC. The most common have inner diameters of 2 to 4.6 mm, and are 15 to 25 cm long. Both 1 mm and micropacked fused silica are also sometimes used. The most common packings are 3 to 5 μm diameter totally porous silica, although many other materials have been used. SFC is a 'normal-phase' technique, making the use of more polar bonded phases commoner. The biggest change from HPLC is the growing use of longer packed columns, as much as 2.2 m in length.

Pumps The most common pumping systems in packed-column SFC use multiple high pressure reciprocating pumps operated as flow control devices. Since the main fluid is supplied in a high pressure gas cylinder, gradient switching valves cannot be used to mix modifier with the fluid in SFC. One high pressure pump is used to deliver the main fluid (SF pump) and another is used to pump modifier(s). Used in conjunction with a back-pressure regulator, properly designed pumps allow independent control of flow, composition and pressure.

The head of the SF pump is chilled to ensure the fluid is pumped as a liquid. However, even as a liquid, the fluids used still have a compressibility much higher than normal liquids. To accurately pump these fluids, the pumps need both an extended compressibility compensation range, and the ability to dynamically change compressibility compensation when the pressure and temperature (and composition) are changed. Slightly modified HPLC pumps usually have an inadequate range of compressibility compensation, and never dynamically compensate for the changes in compressibility which accompany pressure and/or composition changes. Using HPLC pumps for SFC results in highly inaccurate and non-reproducible flows and compositions.

Injection Injection is accomplished using standard HPLC injection valves operated in either fixed or partial loop modes. Care must be exercised in choosing the volume and polarity of the sample solvent. SFC is usually a normal-phase technique. Common sample solvents, like methanol, are stronger solvents than the mobile phase. If too much of such a polar solvent is injected, peaks can be distorted and broadened. Injection volumes up to 10 μL can usually, but not always, be tolerated. Smaller amounts of water can be directly injected but only under carefully chosen conditions. Decreasing the polarity of the sample solvent or injecting smaller amounts reduces or eliminates the problem.

Oven The most common temperature range for packed column SFC with binary or ternary fluids is 30

to 50°C, although both higher and lower temperatures are used. With pure carbon dioxide, the temperature is usually held at >60°C.

Since temperature adjustment often has dramatic impact on selectivity, control of the column temperature is more critical than in HPLC. For the separation of enantiomers, subambient temperatures are often desirable. Ovens similar to GC ovens with cryogenic cooling, Peltier heated/cooled ovens, and recirculating baths are all used.

Pressure control Pressure is controlled using a back-pressure regulator mounted at the downstream end of the system. The BPR is used in conjunction with a pressure transducer and feedback loop. Early regulators were mechanical but today are electromechanical, allowing complex programming of the system outlet pressure. Several commercially available back-pressure regulators have small internal volumes which allow peak collection after the device.

Detection Pure carbon dioxide and the FID and often the UV detector can be used to study fats, waxes, silicones, hydrocarbons and other low polarity solutes, where modified fluids are unusual.

Many other GC detectors are compatible with both pure and modified fluids and have been used with either packed or capillary columns. These include: the electron capture detector (ECD) for the study of explosives, flame retardants, pesticides, derivatives of fatty acids, etc.; the thermionic or nitrogen-phosphorus detector (TID or NPD) for the study of pesticides, caffeine in beverages, and many small drug molecules; the sulfur (petroleum, pesticides) and nitrogen chemiluminescence (similar applications to the NPD) detectors; the flame photometric detector (FPD)(petroleum), as well as others. These detectors are often used with packed columns by splitting off a small fraction of the total column effluent through a fixed restrictor.

There are many hundreds of applications of both pure and modified mobile phases using the UV/VIS detector in the speciality chemical, petroleum, pharmaceutical and agricultural chemical sectors. Standard HPLC UV detectors, including photodiode array detectors, need only a high pressure flow cell to become compatible with SFC (fluid density in the cell approaches 0.9–1 g cm^{-3}). Carbon dioxide is completely transparent to below 190 nm. Mixed with acetonitrile or methanol, short wavelengths can be used to maximize detection limits.

Fluorescence detectors also require a high pressure flow cell, complicated by the need for light paths at 90° to each other. Several high pressure 'chiral' detectors are available for differentiating D and

l isomers. Other detectors that have been successfully used with SFC include: mass spectrometry (MS), Fourier transform infrared (FTIR), and the evaporative light-scattering detectors (ELSD). Most atmospheric pressure ionization HPLC-MS interfaces work equally well, or better, as SFC-MS interfaces.

Future Directions

SFC instrumentation is maturing. The unique requirements for pumping these fluids is slowly becoming widely understood. There are unlikely to be further dramatic improvements in the core technologies. However, a wide range of accessories will appear. As more instruments are sold, the cost of production will tend to drop, making SFC more competitive with HPLC. Development of SFC detector interfaces will continue. Recent results with both mass spectrometry and evaporative light scattering detectors, finally indicate equal or better results than in HPLC-MS, or HPLC-ELSD, but with higher throughput.

User training has been another block to the spread of SFC in industry. One of the chief advantages of packed column SFC in industrial environments, particularly in the pharmaceutical industry, is its similarity with HPLC. Technicians familiar with HPLC have little trouble developing expertise in SFC.

Until recently, SFC has been viewed as a research tool, due largely to the relatively high cost of equipment and the need for an expert operator. As equipment is becoming less expensive, and easier to use, it is beginning to be used in routine analysis. Since the number of analysts involved in research is small compared to the number performing routine analysis, the

incorporation of a technique into routine analysis represents a major expansion. This trend should continue, since the surprisingly low cost of operation and environmental friendliness are becoming more widely understood and appreciated.

Large-Scale Supercritical Fluid Chromatography

Introduction

Preparative supercritical fluid chromatography (Prep-SFC) came about at the same time as analytical supercritical fluid chromatography (SFC). During the 1960s and 1970s at the time of the early development of SFC, several authors included fraction collectors at the outlet of their analytical supercritical fluid (SF) chromatographs. However, the technological difficulties encountered kept these attempts somewhat marginal. The real interest in Prep-SFC appeared in

1982 when Perrut patented large-scale Prep-SFC with eluent recycling. Since then Prep-SFC has been studied and developed by several teams and on various scales. During the past decade commercial equipment has appeared and applications are reaching industry.

Principle

Prep-SFC is the result of the collaboration of three techniques:

- the principle of the separation is the same as in analytical SFC;
- the scale, the application and the industrial interest is the same as preparative high-performance liquid chromatography (Prep-HPLC);

Figure 1 Phase diagram of a pure compound. See the description in the text.

- the economical and practical interest of simple solvent recycling is the same as in industrial supercritical fluid extraction (SFE).

The extensive study of the properties and characteristics of supercritical fluids is not the subject of this article. The main properties relevant to their use in Prep-SFC are good solvent power (comparable to liquids), low viscosity and high diffusion coefficients (intermediate between gases and liquids) and straightforward modulation of solvent properties by pressure adjustment (it is possible to transform a supercritical fluid to a gas by isothermal depressurization).

The principle and characteristics of Prep-SFC can be described with a phase diagram. **Figure 1** shows the eluent cycle in a Prep-SFC process.

At point 1, the eluent is supercritical and the chromatographic separation takes place in the column. At the column outlet, the eluent is depressurized (and heated) to the gas phase at point 2. While in a gas phase the eluent is cleaned and pure fractions collected. The cleaned gaseous eluent is then recycled, through condensation (point 3), recompression (point 4) and heating to the operating temperature (point 1).

This is a description of the simplest Prep-SFC process that uses a pure compound as a supercritical eluent. However, it is often necessary to use a mixture as the supercritical eluent. The secondary component of the eluent is most often a liquid solvent ('the modifier'). A Prep-SFC process that includes a modifier differs from the simple scheme without a modifier and both processes will be described here.

Prep-SFC processes can be classified according to scale. Micro-Prep-SFC is basically the adaptation of an analytical chromatograph to collect small frac-

tions (microgram or milligram size) and is not described here. Laboratory-Prep-SFC is concerned with the purification of larger amounts (hundreds of milligrams or grams). It requires a specific technology, but cannot be considered to be large-scale SFC. It is described briefly later. Pilot-Prep-SFC is intended for the purifications of kilograms per day on columns having an internal diameter of between 5 and 15 cm. It can be used for scale-up studies or even for some small industrial productions. Production-Prep-SFC is for the purification of hundreds of kilograms to tens of metric tons per year. This scale of production takes full advantage of the economics of Prep-SFC.

Important Characteristics

The technique of Prep-SFC is best described by comparing it with Prep-HPLC and the emerging simulated moving bed (SMB) technique, an implementation of countercurrent continuous chromatography.

Prep-HPLC is a very useful tool in the field of high-performance separations. The technique's high flexibility and efficiency means that most separation problems can be solved technically (but not necessarily economically). The main drawback of Prep-HPLC is the huge quantity of expensive solvent that needs to be used. Several strategies have been proposed to eliminate the solvent problem. One of them is SMB which cuts solvent use by up to 10-fold, but needs a higher level of economic investment and is limited to binary separations. Another is Prep-SFC, which reduces the solvent required by a factor of five to 20 (if a modifier is used), or uses no solvent at all (if no modifier is used) but also involves a high level of economic investment and has a limited range of applications.

Selectivity

The range of selectivities accessible by SFC is the same as for HPLC. This is not surprising since selectivity depends on the physical and chemical nature of the stationary and mobile phases. The stationary phases used in Prep-SFC are exactly the same as the ones used in Prep-HPLC. Theoretically, some stationary phases specific to SFC could be used (e.g. cross-linked polymers deposited on a silica support), but phases developed for HPLC are the only ones available in large quantities and, thus, they are the only ones used. Supercritical eluents are fewer in number than the mobile phases used in HPLC and, indeed, carbon dioxide is almost the only supercritical eluent used for Prep-SFC. But the possible use of modifiers, which can be almost any liquid solvent or any mixture, is a powerful parameter for variation of selectivity. Moreover, by changing the operating pressure it

is possible to adjust the solvent strength of the supercritical eluent, since it is compressible, without changing its composition.

The foregoing does not mean that there is no selectivity difference between the two techniques: for a given application, selectivity obtained by SFC can be much higher than by HPLC and vice versa.

Efficiency and Speed

Prep-SFC can attain efficiencies as good as those for Prep-HPLC. A reduction in plate heights of a factor of between two and four are easily obtained leading to efficiencies of between 10 000 and 70 000 plates per metre depending on particle size. Moreover, Prep-SFC has, just like analytical SFC, the advantage of being able to combine high efficiencies with high speed. Indeed, as can be seen in **Figure 2**, in any type of chromatography, a plate height increase (corresponding to a loss of efficiency) is observed when the eluent speed is increased beyond the minimum point. The slope of the curve is correlated to the diffusion coefficient of the sample in the eluent (the higher the diffusivity the smaller the slope). Since diffusion coefficients of supercritical fluids are much smaller than in liquids, the curve is flatter and it is possible to increase the eluent speed (and the productivity) without losing much efficiency. Moreover, in HPLC eluent speed is limited by the pressure drop in the column while in SFC the viscosity of the eluent is much less and such a limitation does not apply. To obtain high efficiencies in large diameter columns, the same difficulties are encountered in Prep-SFC as in Prep-HPLC. For diameters over 5 cm preppacked columns are not

stable enough and lose more than half of their efficiency after a few hours use. This is due to rearrangement of the particles in the column induced by the friction of the flowing solvent. As for Prep-HPLC the solution to this problem is dynamic axial compression columns in which a piston continuously compresses the chromatographic bed, thus preventing the occurrence of voids and the loss of efficiency.

Thermal Degradation

There is no theoretical limit to the operating temperature range of supercritical fluids and some applications use temperatures as high as 200°C. However, the practical temperature range applied to Prep-SFC is from 0 to 100°C and most of the applications are made between 25 and 50°C. These moderate temperatures allow the processing of thermolabile molecules.

Flexibility

The flexibility of use of Prep-SFC is comparable to that of Prep-HPLC. Adjustment of operating parameters to a new feedstock and the start up of a system are simply and quickly performed in a few hours. Prep-SFC is thus well adapted to the type of batch purification often encountered in the pharmaceutical industry. Moreover, separations are not limited to binary separations and it is possible to remove a minor impurity or to isolate one or several compounds from a complex mixture.

Absence or Reduced Use of Solvent

When no modifier is used Prep-SFC can be considered as a 'no-solvent' process because carbon dioxide is used in most cases. The gas is recycled on-line thus there is no solvent consumption, no large storage necessity, no evaporation devices required for downstream processing and no problems with undesirable solvent traces left in the final product. Absence of solvent is also an advantage when it comes to the economics of large-scale separations (see below).

When a modifier has to be mixed with the supercritical main eluent (carbon dioxide), some, but not all, of these advantages are lost. The modifier is added to the eluent concentrations ranging from 0.1 to 25% (more often 1–5%). Thus, only a fraction of the eluent is not recycled on-line which means there is reduced solvent storage and a smaller evaporation plant than for Prep-HPLC. Moreover, the modifier used will very often be a single solvent (not a mixture) which simplifies its evaporation and recycling. The nature of modifiers most often used (methanol, ethanol, isopropanol) means that the toxicity problem of solvent traces left in the final product is

Figure 2 Influence of eluent speed on efficiency. Comparison between high-performance liquid chromatography (HPLC) and supercritical fluid chromatography (SFC).

Figure 3 Scale-up example. Purification of an insecticide.

reduced. Finally, the economic advantage over Prep-HPLC is not completely lost because of the reduced quantity of solvent and its ease of recycling.

Scale-up

Scaling up a method developed in the laboratory can be made easily by multiplying the size of the system (flow rates, injected quantity, section of the column, and so on) by the scale factor. This is possible only if the packing material used is the same and the efficiency of the column is the same (this is possible even on very large columns by dynamic axial compression). Figure 3 gives an example of the scaling up possibility.

Limitations

Large and/or polar compounds have a limited solubility in pure carbon dioxide. As has been already mentioned, in this case it is then necessary to add a modifier to the supercritical eluent to enhance the solubilities. The number of applications amenable to Prep-SFC is greatly increased by the use of modifiers. However, some classes of compounds are still insoluble in carbon dioxide and modifier. An example is that some peptides can be dissolved and processed by SFC, but proteins are outside of the range of Prep-SFC.

Another limitation of Prep-SFC is economic. Investment costs for Prep-SFC are much higher than for Prep-HPLC. Savings on solvent consumption will counterbalance the difference in investment cost only for large- or very large-scale applications. For small- or medium-size applications, where both techniques are applicable, HPLC will often be more economical than SFC.

Implementation

Figure 4 shows a schematic flow diagram of a Prep-SFC. Typical pressures and fluid physical states are also indicated.

Eluent tank

The eluent tank (1) contains carbon dioxide under gas-liquid equilibrium at 4.5 MPa and 10°C. It is a buffer volume in the carbon dioxide loop and its volume is about twice the volume of the column. A molecule of carbon dioxide will pass around the system about 15 times per hour. The external carbon dioxide storage tank needs to be only 50 times the volume of the column for one week of operation (compared with the required storage of solvent in HPLC which is 600–1000 times the volume of the column).

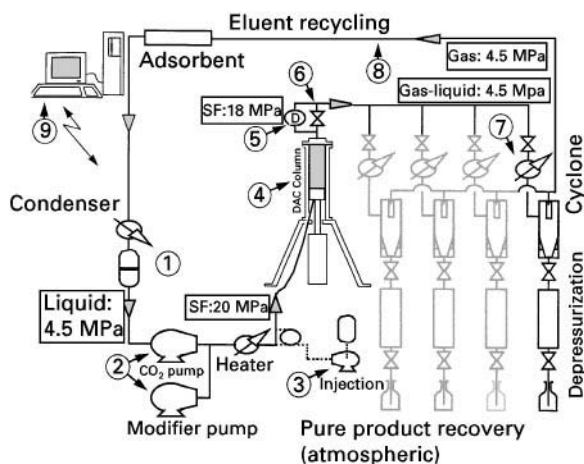

Figure 4 Schematic flow diagram of Prep-SF chromatograph. Legend in text.

Pumps

The carbon dioxide pump (2) is a reciprocating plunger- or membrane-type metering pump. It is a high-pressure pump equipped with one or multiple heads. Pumping is only efficient if the carbon dioxide is kept liquid on the suction side and in the pump head. In order to avoid cavitation it is necessary to cool the eluent tank (1), the suction line and the pump head. Since carbon dioxide is somewhat compressible, reliable pumping is difficult to achieve (the real flow rate differs from the nominal flow rate of the pump) and the efficiency of the pump depends on both inlet and outlet pressures and inlet temperature. Thus, it is better not to rely on the pump to provide a constant flow rate. In the example given the pump is used as a pressure source only, the column inlet pressure is regulated by a pressure regulator and the flow rate is regulated through the depressurization valve (6) at the column outlet. The modifier pump is an ordinary high-pressure liquid metering pump.

Injection Device

For production purposes injections must be made periodically and automatically. The main component of the injection device (3) is a high-pressure metering pump that introduces the sample either directly into the flow of supercritical eluent or into an intermediate injection loop.

Chromatographic Column

The column (4) is similar to Prep-HPLC columns equipped with a dynamic axial compression (DAC) system. A greater thickness of stainless steel is required to withstand the high pressures and a water jacket maintains the operating temperature of the column. Note that, unlike in Prep-HPLC, column outlet pressure is not atmospheric but very close to column inlet pressure (e.g. inlet pressure = 20 MPa and outlet pressure = 18 MPa).

Detector

As in analytical SFC, almost any type of detector (5) can be used (except refractive index detectors): ultraviolet (UV) absorption and so on. UV absorption detectors equipped with a high-pressure cell are used most commonly. Due to the high flow rates, detectors at column outlet must be placed in a split line.

Depressurization Valve

The depressurization valve (6) is a critical piece of equipment. Its function is to reduce the eluent pressure from the operating pressure (e.g. 18 MPa) down

to the recycling line pressure (e.g. 4.5 MPa) and to control the flow rate of the eluent. Depressurization through the valve is almost adiabatic so that it is accompanied by an intense cooling and the fluid at the outlet of the valve is not gaseous but is a gas-liquid mixture (e.g. for carbon dioxide, at 4.5 MPa and 10°C). If the outlet pressure were atmospheric, the physical state of the carbon dioxide would not be a gas-liquid equilibrium but a gas-solid equilibrium (triple point pressure is 0.5 MPa) and the solid would cause random plugging of the tubes. Since the valve is placed at the column outlet, special attention must be given to its design so that it does not include dead volumes that would cause the remixing of the purified fractions.

Traps Lines

A trap line (7) isolates a purified fraction, separates it from the eluent and collects it at atmospheric pressure. There are several ways to achieve this. One configuration is presented in the example which includes a stop valve to select which line is opened when a fraction elutes from the column, a heat exchanger to completely vaporize the carbon dioxide and a cyclone to separate the gaseous carbon dioxide from the liquid sample (or sample dissolved in the modifier). Indeed, the separation cannot be done by a simple decantation, since, after the depressurization, the liquid fraction is highly divided and behaves like a fog that is carried away with the gas. The cyclonic separator is a device that uses the fluid speed to centrifuge it. It has no mechanical moving parts so it is cheap and simple; when properly designed, it can trap 97–100% of the liquid fraction. Also included is a depressurization stage to reduce smoothly the sample pressure from 4.5 MPa to atmospheric pressure.

The number of trap lines required depends on the application. For most industrial processes three to four lines are sufficient. These are a waste line, one or two pure products lines and a mixture line for a fraction requiring recycling (its composition is similar to that of the crude feedstock).

Eluent Recycling

The gas phase is recycled (8). Optionally it can be cleaned with a bed of adsorbents to stop the traces of sample that have not been removed by the cyclones. It is then condensed before being sent back to the eluent tank.

Automation

Although it is possible to imagine a manual version of a Prep-SFC in practice it is almost essential to

Table 1 Examples of production scales

Column diameter (mm)	Column length (cm)	Typical loading capacity		Carbon dioxide flow rate (kg h ⁻¹)
		(g h ⁻¹)	(t year ⁻¹)	
100	10–30	60	0.5	100–200
200	10–30	240	2	400–800
300	10–30	540	4.5	900–1800
500	10–30	1500	12.5	2500–5000

automate. Two pressures, two temperatures and one flow-rate must be controlled. In addition, high-pressure safety and periodic chromatographic functions (injection and collects) must be managed. Finally, data must be acquired and logged.

High-pressure Safety

Supercritical fluids are high-pressure compressible fluids which contain a high level of stored energy that can cause damage if it is abruptly released to atmosphere (unlike high pressure liquids which store little energy because they are not compressible). To prevent any problems associated with pressure release all components are built to withstand pressures much higher than the operating pressure and are certified by regulatory authorities. Safety valves are placed at all critical points in the system and a pressure switch (electromechanical) stops the pressure source (the pump) in case of overpressure. The pump may also incorporate a device to prevent it reaching pressures higher than the maximum operating pressure. Finally, sensors placed all around the system are automatically monitored to prevent any safety problems.

Prep-SFC: What Scale?

Table 1 gives examples of the production scales obtained with different column diameters. These are only typical figures and, depending on the application, actual figures can be bigger or smaller. Pilot or production Prep-SFC can be used for purification of hundreds of grams in a week or for tens of tons in a year as is shown in Tables 2 and 3.

Table 2

3 g (per injection on a 100 mm internal diameter column)
 × 6 (injections per hour)
 × 24 (hours per day)
 × 4 (days per week)
 = 1.7 kg per week

Variants

Working Modes

Various working modes can be implemented in Prep-SFC. They include pressure and/or composition gradients and simulated moving bed SFC (SMB-SFC). Although these techniques may be useful in theory, they are rarely justified by practice and economics. Pressure or composition gradients can be used for selectivity enhancement and/or elution time reduction when the feedstock components have a large range of retention factors. However, with gradients, one of the advantages of Prep-SFC, the speed, is lost since time is required between the two injections to restore the initial pressure or composition, whereas in isocratic Prep-SFC, one can inject the next sample before the previous one is completely eluted.

SMB-SFC offers some of the theoretical advantages of its related technique SMB-HPLC. In SMB-SFC, the feed introduction and the product removal are continuous. The stationary phase is used more efficiently due to the countercurrent process. In SMB-HPLC the high complexity of the system is counterbalanced by savings on the mobile phase consumption, but this is not the case in SMB-SFC because the eluent is already recycled. However, in SMB-HPLC, the elution is necessarily isocratic while in SMB-SFC it is possible to create a pressure gradient in the system and, in some cases, this advantage can bring a decisive productivity increase.

Operating Options

The system described earlier is not the only possible way to implement Prep-SFC. For instance, one can

Table 3

250 g (per injection on a 500 mm internal diameter column)
 × 6 (injections per hour)
 × 24 (hours per day)
 × 300 (days per year)
 = 10.8 t year⁻¹

choose to regulate the flow rate by controlling the pump speed and to control the column outlet pressure by the depressurization valve. The carbon dioxide pressure in the traps can be reduced to atmospheric pressure and the condenser can be replaced by a compressor. It is also possible to add the modifier on the suction side of the main eluent pump.

Applications

Although the principle of Prep-SFC is well established, its commercial availability is relatively new so that there are only a limited number of published applications. One of the first and most studied applications with an industrial opening is the purification of ω -3 unsaturated fatty acids from fish-oil extracts. More precisely, the ethyl esters of eico-sapentaenoic acid ($C_{22:5}$) and docosahexaenoic acid ($C_{20:6}$) are required at a relatively high purity. Pure carbon dioxide is used as an eluent. There is no difficulty in solubilizing the ethyl esters. Large-scale production is envisaged (tens of tons per year). The costing of the process shows that separation by Prep-SFC is two to five times cheaper than Prep-HPLC and the quality of the final product is better.

More recently, other applications have been patented among which one important example is the purification of cyclosporine (a cyclic undecapeptide) with carbon dioxide and an alcohol as modifier. Among the emerging applications under study many chiral separations are candidates to be performed by Prep-SFC. One separation example described below in more detail has been developed in the authors' facilities.

Cis-trans Isomer Separation of Phytol

The separation of the *cis*- and *trans*-isomers of phytol has been chosen as an application of Prep-SFC using carbon dioxide and a modifier (isopropanol) as eluent (see Figure 5).

Phytol is a fatty alcohol and its *trans*-isomer is used in perfumery. The separation has been done on laboratory-scale equipment and has been extrapolated to industrial production. The main steps of the optimization procedure are given below.

Figure 5 Molecular structure of phytol.

Stationary phase Apolar bonded phases and polymeric phases have been rapidly eliminated because of a lack of selectivity. A classical silica stationary phase was found to give the best separation.

Mobile phase Pure carbon dioxide will not elute the sample so it is necessary to add a modifier. Three alcohols have been tested: methanol (MeOH), ethanol (EtOH) and isopropanol (IPA); IPA gives the best selectivity (see Figure 6).

Overloading The first overloading trials have shown that the thermodynamics of the separation is governed by a concave upward adsorption isotherm (low concentrations migrate faster through the column than high concentrations) even for rather small loadings (10 μ L on a 10 mm internal diameter column). This phenomenon can be clearly seen in Figure 7.

Temperature A rapid screening of operating temperatures in the range of 10–80°C shows the influence of this parameter (see Figure 8). The intermediate temperature (50°C) was chosen to maintain good resolution and short cycle time.

Pressure and modifier content A rapid screening of these two parameters led us to choose 25 MPa and 5.5% (w/w) of IPA in carbon dioxide.

Preliminary trial After establishing the optimum conditions above a preliminary injection was carried out to give the chromatogram shown in Figure 9.

The 4-min cycle time refers to the time elapsed between two successive injections. The total chromatogram duration is 6 min but it is not necessary to wait for the previous injection to be completely eluted before the next injection. With this overlapping injection procedure, the late eluted impurities of the first injection will elute together with the early eluted impurities of the second injection and a 50% increase in productivity is obtained in this particular case. This short cycle time is an advantageous characteristic of Prep-SFC compared to Prep-HPLC where cycle times are closer to 30 min.

Small-scale production On the basis of these results production has been carried out. Figure 10 shows the chromatogram of the repeated injections and Table 4 gives the results of this production step.

Extrapolation of these results to large-scale production can be made directly with a 300 mm internal diameter column and gives 2.3 t year⁻¹ production of the *trans*-isomer from 4 t of feedstock with a product purity of 97.8% and a recovery of greater than 80%.

Figure 6 Phytol purification; modifier selection. Stationary phase: silica 15 μm , 100 \AA , AMICON; column: 10 mm \times 250 mm; temperature 50°C; pressure 25 MPa; carbon dioxide flow rate 13.5 g min⁻¹; modifier: MeOH, EtOH or IPA at 0.5 mL min⁻¹ (2.9% w/w); sample: phytol mixture 10 μL .

Figure 7 Phytol purification. Peaks distortion due to overload. Modifier: IPA; sample: crude phytol 10, 20, 40, 60, and 100 μL ; other conditions as in Figure 6.

Figure 8 Phytol separation. Influence of temperature. Temperature: 10, 50 and 80°C. Phytol crude: 10, 60, and 100 μL ; other conditions as in Figure 7.

Figure 9 Chromatogram preliminary to production test. Stationary phase: silica 15 μm , 100 Å, AMICON; column: 10 mm \times 250 mm; temperature 50°C; pressure 25 MPa; carbon dioxide flow rate: 13.5 g min⁻¹; modifier: IPA at 1 mL min⁻¹ (5.5% w/w); sample: crude phytol 60 μL = 50.5 mg undiluted; detection: UV absorption at 220 nm.

Economics of Prep SFC

The economics of a separation process depend greatly on the specific application. Indeed, the same Prep-SFC equipment can purify 1 kg per day or 50 kg per day depending on the cycle time, the loadability of the column, the solubility of the sample, the selectivity between the compounds in the sample, and the required purity and recovery. However, it is possible to give the main features of the cost of a separation by Prep-SFC and a reasonable range of costs.

Figure 11 shows a cost breakdown of a typical industrial separation using pure carbon dioxide and no modifier. The total purification cost for this example is about US\$100 per kilogram injected. The range for such a case is US\$20–200 per kilogram. One can see that the capital outlay is half of the total cost while the eluent cost (carbon dioxide) is negligible (2%). The high capital cost is a consequence of working at high pressure and the low cost of the eluent is a consequence of the total on-line recycling of a cheap solvent.

Figure 12 shows the cost breakdown of a typical industrial separation using carbon dioxide and modifier. The total purification cost for this example is

Figure 10 Phytol separation. Preparative chromatogram. Conditions as in Figure 9. One injection every 4 min.

about US\$280 per kilogram injected. The range for such a case is US\$40–400 per kilogram. By comparison with the previous example, the capital cost is slightly higher (an additional pump and bigger traps) and the recycling of the modifier represents 15–30% of the total purification cost. The other costs are similar.

The structure of these cost breakdowns can be compared with Prep-HPLC where the cost of the solvent losses and solvent recycling can represent 60% of the total purification costs. Since an increase in production scale is accompanied by a large decrease of the relative costs (per kilogram of product) except for the consumables (solvent and stationary phase), the purification costs by Prep-SFC and Prep-HPLC will have the tendencies shown in Figure 13 and the choice between Prep-SFC and Prep-HPLC depends on the scale of the purification envisaged. Large scales of production are highly favourable to Prep-SFC.

Lab-Prep-SFC

Lab-Prep-SFC is the purification of hundreds of milligrams or gram quantities. The column internal diameter is typically 10 or 20 mm and the carbon dioxide flow rate is between 10 and 60 g min⁻¹. It is

Table 4 Phytol separation—preparative step results

	Impurities	cis-Isomer	trans-Isomer	Mass of fractions (g)
Crude	7.6%	34.2%	58.2%	1.06
Fraction 2	0.2%	99.3%	0.5%	0.28
Fraction 3	0%	77.2%	22.8%	0.04
Fraction 4	0.2%	2%	97.8%	0.5
Fraction 5	60.6%	5%	34.4%	0.19

One gram of crude has been injected in 1.5 hours on a 10 mm ID column. 95% of the injected material has been collected in four fractions. The *cis*- and *trans*-isomers have been collected with high purities. Only 68 g of IPA were used for the production.

Figure 11 Typical cost of separation by Prep-SFC for a production of 3 t year⁻¹ injected on a 200 mm internal diameter column using pure carbon dioxide as an eluent.

used for two different purposes: application studies preliminary to scale up (see the earlier example) and sample purification for research purpose.

The principle of Lab-Prep-SFC is the same as large-scale Prep-SFC but its technology is slightly different. It is possible, but not necessary, to recycle the carbon dioxide and the columns do not require dynamic axial compression and are slurry prepacked. A UV absorption detector can be installed on-line, and an automated injection device is required for repeated injections, but individual injection facilities by way of a manual injection loop are also necessary for evaluation study purposes.

The interest of Prep-SFC at this scale is not in terms of cost as we have seen that the effect of the savings on solvent is only sensible for large-scale applications. Users of Lab-Prep-SFC are mainly pharmaceutical

Figure 12 Typical cost of separation by Prep-SFC for a production of 1.6 t year⁻¹ injected on a 200 mm internal diameter column using carbon dioxide and modifier as an eluent.

Figure 13 Dependence of the purification costs of Prep-SFC and Prep-HPLC on the scale of purification. Packing, labour and miscellaneous costs have not been included because they are similar for the two processes.

laboratory researchers who find in SFC a way to reduce the quantity of solvents stored in their laboratory and who appreciate the speed of both method development and purification. Then, the interest of Prep-SFC is not measured in dollars per kilogram, but in the number of samples processed per week.

Conclusions

Prep-SFC is a powerful separation technique that gives high purities for difficult separations. The main advantages of this technique can be summed up by comparison with Prep-HPLC: it solves (or considerably reduces) the problems associated with solvents, it is economical at a large scale and fast at a small scale. Its limitations are the relatively high level of investment required and the restricted range of applications due to the low solubility of many biological macromolecules. Given this fact, one can conclude that the principal technical and economic domains of application of Prep-SFC are in the pharmaceutical industry and the high value compounds of the food and fine chemical industries. One can predict that Prep-SFC will not replace Prep-HPLC but should take 15–25% of its market share.

Theory of Supercritical Fluid Chromatography

K. D. Bartle, University of Leeds, Leeds, UK

Copyright © 2000 Academic Press

Introduction

The practising analyst requires of any separation technique that it should provide rapid and efficient resolution of mixtures. The relevant theory, therefore, is concerned with factors which influence chromatographic retention and resolution, and with variables influencing injection and detection.

The special properties of supercritical fluids make them unique chromatographic mobile phases, and the development of supercritical fluid chromatography (SFC) to make use of these properties has been discussed elsewhere. Here, the theory underlying SFC chromatographic parameters is described.

Retention in SFC

SFC is unique among chromatographic techniques in having four variables to change retention: temperature, density or pressure, and mobile-phase composition.

Effect of Column Temperature

The temperature, T , at which an analysis is carried out has an important influence on retention. At constant pressure the retention factor, k , may be either increased or decreased (Figure 1) by increasing the temperature, because of the combined influences of solubility in the stationary and mobile phases, and on vapour pressure, so that resolution may be tuned by adjusting T . A rigorous expression which accounts for the variation of SFC retention with temperature at constant pressure is:

$$\ln k - \ln \phi_m + \ln \left(\frac{\rho}{c^\theta} \right) = C + \frac{\Delta S_s^\theta}{R} - \frac{PV + \Delta H_s^\theta}{RT}$$

[1]

where ϕ_m is the fugacity coefficient of the solute in the mobile phase, ρ is the density of the supercritical fluid, c^θ is the standard concentration and C is a constant. ΔH_s^θ and ΔS_s^θ are respectively the partial molar enthalpy and entropy of solution of the solute in the stationary phase.

The left-hand side of eqn [1] is obtained as follows: experimental values of k ; values of ρ/c^θ from the

Figure 1 Capacity ratios of pyrene as a function of column end pressure (P_e) and temperature (T). Three-dimensional network shown in two perspectives. Conditions: 25 cm \times 4.6 mm i.d. packed column, 10 μ m silica particles; n -pentane. IUPAC (International Union of Pure and Applied Chemistry) equation of state for CO₂; and values for ϕ_m are calculated from the Peng–Robinson equation of state. This relationship has been tested for a number of hydrocarbon solutes. Figure 2 shows the individual contributions and total of the left-hand side of eqn [1] for fluorene. It can be seen how the addition of the steepening curves for both $(\ln \rho/c^\theta)$ and $\ln \phi_m$ to the curve of $\ln k$, with its maximum, gives a total which is approximately a straight line when plotted against $1/T$.

The dependence of retention on temperature at constant density is simpler and is predicted via the van't Hoff equation:

$$\frac{d \ln k}{d(1/T)} = -\frac{\Delta H_T^\theta}{R} \quad [2]$$

where ΔH_T^θ is the enthalpy of transfer of solute between phases. It follows that $\ln k$ is a linear function of $1/T$ and that increasing the analysis temperature at constant density always results in a decrease in k .

Figure 2 Contributions to $(\ln k + \ln (\rho/c^\theta) - \ln \phi_m)$ for fluorene as a function of reciprocal temperature. Squares, $\ln k$; continuous line, $\ln (\rho/c^\theta)$; dashed line, $\ln \phi_m$; circles, $(\ln k + \ln (\rho/c^\theta) - \ln \phi_m)$. Effect of Mobile-Phase Density

SFC retention is related to the solubility in the mobile phase and hence to its density, which is varied by changing the pressure. SFC chromatographs usually have software to calculate the pressure necessary to achieve a given density at a given temperature from polynomials fitted to the pressure/density isotherm. Programmed elution is achieved by changing the pressure during the run – the analogue of temperature programming in gas chromatography (GC) and gradient elution in high performance liquid chromatography (HPLC).

The rate of density programming of a homologous series is determined from the relation:

$$\ln k = A_0 + B_0 n - mn\rho \quad [3]$$

where A_0 , B_0 and m are constants, ρ is the density and n is the carbon number of the member of the series. From eqn [3], it can be shown that:

$$\rho = \frac{B_0}{m} - \frac{1}{mn} \quad [4]$$

where $B_0/m = \rho_A$ is the density at which all members of the series co-elute. Thus, as ρ approaches ρ_A , resolution decreases as linear density programming elutes successive members of the series. To elute members of the series at regular time intervals:

$$n = j(t + t') \quad [5]$$

where j is a constant and t' is the reference elution time.

Hence:

$$\rho = \rho_A - \frac{K}{t + t'} \quad [6]$$

where K is another constant. It follows that, if ρ_A is known, homologues can be eluted regularly by asymptotic density programming. ρ_A may be determined from a graph of elution density versus $1/n$ in a linear density run by extrapolation to $1/n = 0$.

It is noteworthy that, as ρ increases, the diffusion coefficient of the solute decreases with concomitant increase of the plate height and loss of resolution. To offset this, the column temperature may be increased during density programming. However, since increasing temperature increases solute vapour pressure and hence solubility (see above), the above approach does not hold when density and temperature programming are combined. In fact, the combined influence of

column pressure, P , and temperature, T , on retention and resolution may be demonstrated by three-dimensional diagrams in which k or mean resolution is plotted versus P or T (Figure 1). Once the general shape of such diagrams is known for a given class of substrate, only a few chromatograms are required to determine how P and T must be changed to improve resolution.

Mobile-Phase Composition

Even high densities of CO_2 may be insufficient to permit migration of certain solutes, and the addition of polar modifiers may be necessary. Chromatographic retention may then be empirically expressed by:

$$k = ax^2 + bx + c \quad [7]$$

where a , b and c are constants and x is the mole fraction of organic modifier. The constant a is often small, so that retention decreases linearly as the mole fraction of organic modifier is increased.

A second approach models SFC retention in terms of solute solubility in the mobile phase via the Hildebrand solubility parameter: δ_s for the stationary phase, δ_m for the mobile phase and δ_i for the solute. The retention variation is represented here by:

$$\ln k = \frac{V_i}{RT}(\delta_m + \delta_s - 2\delta_i)(\delta_m - \delta_s) + \ln\left(\frac{n_s}{n_m}\right) \quad [8]$$

where V_i is the molar volume of the solute, n_s the total number of moles of the stationary phase and n_m the total number of moles of mobile phase. This approach predicts a decrease in retention with increasing modifier content if $\delta_m < \delta_i$, a retention minimum when $\delta_m = \delta_i$, and a retention increase when $\delta_m > \delta_i$. Such correlations are not always observed, and the dielectric constant has also been invoked as a predictor of retention.

Role of the Stationary Phase

The stationary phase influences retention in SFC, as in all chromatography, through interactions with the solute: dispersive, dipole-dipole, dipole-induced and hydrogen-bonding acidic and basic interactions are all possible and retention can be modelled by means of solubility parameters, respectively δ_d , δ_o , δ_{in} , δ_a and δ_b . Retention is then described by:

$$\ln k = V_i(a\delta_d + b\delta_o + c\delta_{in} + d\delta_a + e\delta_b + f) \quad [9]$$

where V_i is the solute molar volume and a - f are weighting factors for given stationary and mobile phases at a given temperature.

The coefficients a - f for each combination can be deduced by means of values of k for probe solutes for which solubility parameters and molar volumes are known. These coefficients then allow retention to be predicted for other solutes, solubility parameters of which have been calculated. In fact, the five individual solubility parameters can be calculated from refractive indices, dipole moments and energies of hydrogen bonding, with calibration using compounds for which relevant data are available. With values for the coefficients a - f and the solubility parameters for a given compound, k for a given mobile and stationary phase is then obtained from eqn [9].

Retention factors and solubility parameters for each probe molecule, stationary phase and mobile phase are combined into an expression of the form of eqn [9]. The series of simultaneous equations is then solved, using a matrix, to give values of the coefficients a - f for each stationary/mobile-phase combination. The coefficients vary greatly on moving from pure CO_2 to 1% modifier, thereafter showing a more gradual variation with increasing modifier content in the mobile phase; this observation is consistent with the formation of a thin layer of modifier on the stationary phase. The coefficients a - f are a measure of the ability of the stationary phase to take part in the five different types of molecular interaction.

Use of the coefficients a - f , solubility parameter and molar volume substituted into eqn [9] yield predicted k values in fair agreement with experimental data. Correspondingly, solubility parameters for compounds for which they are not otherwise available may be obtained. The model has also been extended to difunctional compounds.

Resolution in SFC

Separation in all chromatography and chromatographic theory is defined by the resolution, R_s , between two component peaks:

$$R_s = \frac{\Delta t}{w} \quad [10]$$

where Δt is the separation between peak maxima, and w is the mean baseline peak width. Baseline (99.9%) resolution corresponds to $R_s = 1.5$. The resolution is determined by the number of theoretical plates, N , the capacity factor, k , and the selectivity, $\alpha (= k_1/k_2)$, by:

$$R_s = \frac{N^{1/2}}{4} \left(\frac{\alpha - 1}{\alpha} \right) \left(\frac{k}{1 + k} \right) \quad [11]$$

For a compound with retention time t_R , N is given by:

$$N = 16 \left(\frac{t_R}{w} \right)^2 \quad [12]$$

The column length or height equivalent to a theoretical plate (HETP) is related to average linear mobile phase velocity, \bar{u} , by:

$$H = A + \frac{B}{\bar{u}} + C_m \bar{u} + C_s \bar{u} \quad [13]$$

The A , or multiple-path term, is zero for a capillary column, but, for a packed column:

$$A = 2\lambda d_p \quad [14]$$

where d_p is column packing particle diameter and λ is a constant related to the eddy diffusion coefficient.

The B term defines that portion of H caused by longitudinal diffusion during passage down the column and is given by:

$$B = 2D_M \quad [15]$$

where D_M is the diffusion coefficient of the solute in the mobile phase.

C_m arises from the resistance to mass transfer in the mobile phase, and is proportional to d_c^2/D_M , where d_c is the column diameter for a capillary and the

particle diameter, d_p , for a packed column. C_s , the contribution from solute diffusion in the stationary phase, is proportional to d_F^2/D_s where d_F is film thickness and D_s , the diffusion coefficient in the stationary phase, is generally negligible for a thin coating.

Differentiation of eqn [13] allows the optimum mobile-phase velocity (i.e. for minimum HETP, H_{\min}) to be written as:

$$\bar{u}_{\text{opt}} = \left(\frac{B}{C_m} \right)^{1/2} \quad [16]$$

$$H_{\min} = A + 2(BC)^{1/2} \quad [17]$$

It follows that H_{\min} depends only on k and d so that SFC and HPLC on the same column can only be carried out with the same maximum plate number. Similar considerations hold for SFC and GC (Figure 3). However, \bar{u}_{opt} depends on D_M and is much greater in SFC than in HPLC because of the greater diffusivity of solutes in supercritical fluids; it follows that SFC on a packed column is much more rapid than HPLC on the same column (see Figure 3 and below). Because D_M is less for a supercritical fluid than a gas, however, speed of analysis in capillary SFC is much reduced in comparison with GC. To offset this effect, capillary column diameters of 50 μm

Figure 3 Efficiency as a function of mobile-phase velocity. Commonly used efficiency velocity ranges are highlighted. Packed column conditions: 5 μm particles, values calculated from the Knox equation with $A = 1$, $B = 2$, $C = 0.05$ (for LC), and $C = 0.5$ (for SFC). Open tubular column conditions: 50 μm i.d. (SFC), 300 μm i.d. (GC), values calculated from the Golay equation with $k = 5$. Values for D_m were $10^{-5} \text{ cm}^2 \text{ s}^{-1}$ for liquid, $2 \times 10^{-4} \text{ cm}^2 \text{ s}^{-1}$ for high density supercritical fluid (100°C), $5 \times 10^{-4} \text{ cm}^2 \text{ s}^{-1}$ for low density supercritical fluid (100°C), and $10^{-1} \text{ cm}^2 \text{ s}^{-1}$ for gas.

Figure 4 Efficiencies for different column diameters.

are the norm in SFC; in fact, capillary SFC is still often comparatively slow and a column diameter of 25 μm would be desirable. The dependence of C_m on d_c^2 also leads to small preferred column diameters for capillary SFC. Figure 4 illustrates the effect of column diameter on column efficiency.

Speed of Analysis

The analysis time in chromatography for a given solute is calculated from:

$$t_R = \frac{L}{\bar{u}}(1 + k) \quad [18]$$

The relative speed of analysis of packed and capillary column SFC may be compared by means of the parameter H_{\min}/u_{opt} . For values of k between 1 and 5:

$$\begin{aligned} \frac{H_{\min}}{u_{\text{opt}}} &= \frac{2d_p^2}{3D_M} \\ \frac{H_{\min}}{u_{\text{opt}}} &= 0.1 \frac{d_c^2}{D_M} \end{aligned} \quad [19]$$

For equal speeds of analysis, therefore, $d_c = 2.6d_p$. For a given separation, it follows that analysis on currently available capillary columns with i.d. 50 μm is much slower than on columns packed with 3 or 5 μm particles.

On the other hand, speed of analysis is of no value if resolution, i.e. plate number, is insufficient. For equal pressure drops across capillary (maximum plate number N_c) and packed (maximum plate number N_p) columns:

$$\frac{N_c}{N_p} = 4.6 \left(\frac{d_c}{d_p} \right)^2 \quad [20]$$

Hence, from this analysis, a 50 μm capillary generates 450 times as many plates as a column packed with 5 μm particles. However, if N is set at 5000 plates for both columns, a typical ratio of analysis times would be 2.5 in favour of the packed column.

Injector and Detector Requirements

In packed column SFC, injection is normally carried out by switching the contents of a sample loop into the mobile phase. Flow and column diameter here do not generally affect separation efficiency. For capillary SFC, much smaller injected volumes are required, and these are introduced by splitting the injected sample, or more usually by time-split injection, in which the injection valve is opened and closed very rapidly by pneumatic operation. A retention gap, located before the column, may permit focusing of larger amounts of sample. Injection volumes are determined from a general equation which relates τ_i and τ_c , the standard deviations in the peak widths due to the injector (or detector) and the column. N and N_i are respectively the number of theoretical plates provided by the column and the number of those

filled by injector or detector or detector volume:

$$\frac{\tau_i}{\tau_c} = \frac{N_i \left(\frac{n}{k} \right)^{1/2}}{N \left(\frac{n}{k} \right)^{1/2}} \quad [21]$$

From eqn [21], an expression has been derived linking fractional loss of resolution, ΔR_s , due to the injector or detector volume to column and retention characteristics:

$$v_i = 0.866\pi d_c^2 (LH)^{1/2} \left[\frac{1}{(1 - \Delta R_s)^2} - 1 \right]^{1/2} (1 + k) \quad [22]$$

where v_i is the injection volume and L is column length. Since H is a function of d_c , v_i is proportional to $d_c^{5/2}$ and for a $10 \text{ m} \times 50 \text{ }\mu\text{m}$ column operated under practical conditions, a 1% loss of resolution requires an injection volume of only 50 nL.

For equal distribution coefficients, K_D , an equation relating the maximum loadabilities, L_p and L_c , for packed and open tubular columns has been derived:

$$\frac{L_p}{L_c} = 1.24 \left(\frac{d_{pc}}{d_c} \right)^2 \left[\frac{1 + \frac{K_D \varepsilon_i (1 - \varepsilon_e)}{\varepsilon_T}}{1 + \frac{4K_D d_F}{d_c}} \right] \left(\frac{L_p}{L_c} \right)^{1/2} \left(\frac{d_p}{d_c} \right)^{1/2} \quad [23]$$

where d_{pc} is the diameter of the packed column; ε_i , ε_e and ε_T are intraparticle, interstitial and total porosities, respectively; and L_p and L_c are the lengths of the packed and open tubular columns, respectively.

Table 1 lists the maximum sample loadability ratios for different K_D values for typical packed and open tubular columns; as might be expected, sample loadabilities are much greater on packed columns.

Table 1 Sample loadability ratios for different distribution coefficients

K_D	$\frac{L_p}{L_c}$
1	31
10	101
100	373

Packed column: $L_t = 20 \text{ cm}$; $d_o = 5 \text{ }\mu\text{m}$; $d_{oc} = 1 \text{ mm}$; $\varepsilon_i = 0.5$; $\varepsilon_e = 0.4$; $\varepsilon_T = 0.7$. Open tubular column: $L_c = 10 \text{ m}$; $d_c = 50 \text{ }\mu\text{m}$; $d_F = 0.2 \text{ }\mu\text{m}$.

Increasing the column diameter is the simplest approach to increasing the sample capacity of packed columns, since the surface area of stationary-phase support particles is generally maximized. However, for capillary columns, sample capacity can be increased by increasing the stationary phase film thickness, d_F . This should also lead, in theory, to a reduction in column efficiency but in practice such a reduction is only small, with film thickness up to $1 \text{ }\mu\text{m}$.

CHROMATOGRAPHY: THIN-LAYER (PLANAR)

Densitometry and Image Analysis

P. E. Wall, Merck Limited, Poole, Dorset, UK

Copyright © 2000 Academic Press

Introduction

Densitometry is a means of measuring the concentration of chromatographic zones on the developed thin-layer chromatography high performance thin-layer chromatography (TLC in HPTLC) layer. The instrument does this without disturbing the substance in the chromatogram. The method and computer-controlled instrumentation produces results that are not only

reproducible, but also highly accurate ($\sim 1\%$ standard deviation). Scanning is a fast process (up to a scan speed of 100 mm s^{-1}) with a spatial resolution in steps from 25 to $200 \mu\text{m}$. Full UV/visible spectra (190–800 nm wavelength) of separated analytes can be recorded at high speed and peaks can be checked for purity by obtaining and comparing spectra from the start, middle and end of the peaks. With the use of highly sensitive charged coupled device (CCD) cameras, the photographic image of the developed TLC/HPTLC plate can be stored as a video image. This can be video-scanned to determine the concentration of separated components or can be printed when required as part of a document for a permanent record of the results. Many images can be stored on the computer hard drive and archived whenever required.

The Development of Modern Scanning Densitometry

The results of a developed TLC/HPTLC plate or sheet can be quantified in a number of ways. Visually, an estimate of concentration can be made. Many related substance tests in the pharmacopoeias rely on the concentration of the sample impurities being less than the standard concentration as seen visually. These are limit tests which depend on the eye of the observer determining that the concentration of the unknown is less than that of the standard. It has been estimated that the human eye can detect down to about $1 \mu\text{g}$ of a coloured spot on a TLC plate with a reproducibility of about 10–30%.

Better quantification can be obtained by eluting the relevant chromatographic zone from the adsorbent followed by spectrophotometry. The position of the zone can be marked out with a sharp bradawl and a microspatula used to scrape away the zone. These scrapings are then transferred to a container where a suitable solvent can be used to dissolve the compounds of interest from the particles of the adsorbent. The mixture is filtered and the concentration of the analyte in solution determined by transmittance/absorption spectrophotometry. There is little to recommend in this procedure as it is both tedious and time-consuming. It also requires meticulous care as errors can easily creep into the procedure. It is difficult to ensure that all the sample is completely removed from the TLC layer and is transferred from the chromatographic zone for further work-up if it is not easily seen in the visible or UV parts of the spectrum.

The technique of scanning densitometry determines the concentration *in situ*. It scans at set spectral wavelengths and does not rely on removal of any of the chromatographic zones from the TLC/HPTLC plate. Hence the previous problems and errors are

eliminated. Scanning densitometry dates back to the 1950s when it was used to scan thin strips of paper chromatograms containing separated amino acids. Since then these primitive instruments have undergone considerable change, to the extent that they are now advanced analytical tools of similar capabilities to modern HPLC instrumentation.

Today's scanning densitometer measures reflectance, quenched fluorescence or fluorescence induced by electromagnetic radiation. For this reason, the instrument is now described as a spectrodensitometer. Although all three detection modes are commonly used, fluorescence is limited by the fact that fewer substances can be induced to fluoresce. Many spectrodensitometers also have an attachment for scanning electrophoresis gels by transmission.

The principle of operation is based on light of a predetermined beam size and wavelength striking the thin-layer surface perpendicularly whilst the TLC plate moves at a set speed under the stationary beam, or alternatively the beam traverses the stationary plate. Some of the electromagnetic radiation passes into and through the layer (transmitted light) whilst the remainder, due to the opaqueness of the layer, is reflected back from the surface. When the light beam passes over an absorbing chromatographic zone, there is a difference in optical response and less of the light is reflected (or transmitted). A photoelectric cell is used to measure the reflected light. When this receives a reduced amount of reflected light due to the presence of an absorbing chromatographic zone, a means is provided of detecting and quantifying the analyte.

Fluorescence quenching mode is really a variation on absorption methods. An inorganic phosphorescent indicator or organic fluorescent indicator is incorporated into the adsorbent layer. The inorganic phosphors give either a bright green or pale blue phosphorescence depending on the compound used. The phosphorescence is very short-lived. Hence it is best observed by continual exposure to UV light at 254 nm. Most HPTLC plates contain the indicator which exhibits the pale blue phosphorescence. This indicator is acid-resistant and allows higher sensitivity of detection of separated analytes due to less intense and less 'noisy' backgrounds. TLC plates containing organic fluorescers which give a bright blue fluorescence when excited by UV light of 366 nm are not as popular. Following chromatographic development, the plates incorporating the fluorophore are scanned at 254 or 366 nm in the absorbance mode. As the sample components absorb the excited radiation, the intensity of the phosphorescence or fluorescence is diminished. Consequently a variation occurs in the reflected light detected by the photomultiplier (or photoelectric cell).

When separated analytes naturally fluoresce under UV light, the spectrodensitometer can be used to scan in the fluorescence mode. The UV light provides the energy in these instances to excite electrons in molecules of the analytes from a ground state to an excited singlet state. As the excited electrons return to the ground state, energy is emitted as radiation at a longer wavelength, usually in the visible range. For best results in using this technique, it is important to use TLC/HPTLC plates which do not contain a phosphorescent or fluorescent indicator to minimize background interference.

Theory of Spectrodensitometry

In spectrophotometric measurements where the absorbance is measured as a result of a beam of light of set wavelength passing through a fixed pathlength of solution, a direct relationship exists between the observed absorbance and the concentration of the solution. This is known as Beer's law. However, it should be pointed out that this relationship is not linear over the whole range of concentration, and it depends on the sample solution being transparent.

As TLC/HPTLC plates are opaque, a somewhat different approach is required. In the 1930s Kubelka and Munk investigated the relationship between absorbance, transmission and reflectance, deriving mathematical expressions to explain the effects of absorbance and reflectance. When a ray of incident light comes into contact with the surface of the opaque TLC layer, some light is transmitted, some is reflected in all directions at the surface and some rays are propagated in all directions inside the adsorbent. The theory which explains to a large degree what is happening in this process is known as the Kubelka-Munk theory. Certain assumptions can be made which simplify the mathematical equations derived. The theory assumes that both the transmitted and reflected components of incident light are made up only of rays propagated inside the sorbent in a direction perpendicular to the plane of the surface. All other directions will lead to longer pathways and hence stronger absorption. These rays therefore contribute little to either the transmitted or reflected light and their contribution can be treated as negligible. When light exits from the sorbent at the layer-air boundary, light scattering occurs, and it is distributed over all possible angles with the surface.

The coefficient of light scatter (S), can therefore be proposed; this depends on the layer thickness. If we assume that this is unchanged in the presence of a chromatographic zone, the following equation can be derived for an infinitely thick opaque layer:

$$\frac{(1 - R_{\infty})^2}{2R_{\infty}} = \frac{2.303}{S} \cdot a_m \cdot C \quad [1]$$

where R_{∞} is the reflectance for an infinitely thick opaque layer, a_m is the molar absorptivity of the sample, c is the molar concentration of the sample and S is the coefficient of scatter per unit thickness.

This equation is clearly less than ideal as the layer has a finite thickness. More meaningful expressions for the intensity of the reflected light, I_R , and the transmitted light, I_T , for a layer of thickness (l) are given by the following hyperbolic solutions:

$$I_R = \frac{\sinh(b \cdot S \cdot l)}{a \cdot \sinh(b \cdot S \cdot l) + b \cdot \cosh(b \cdot S \cdot l)} \quad [2]$$

$$I_T = \frac{b}{a \cdot \sinh(b \cdot S \cdot l) + b \cdot \cosh(b \cdot S \cdot l)} \quad [3]$$

where

$$a = \frac{S \cdot l + K_A \cdot l}{S \cdot l}$$

and

$$b = (a^2 - 1)^{1/2}$$

K_A is the coefficient of absorption per unit thickness.

The application of the equations to quantitative analysis in TLC is quite complex, but it can be greatly simplified by making a number of reasonable assumptions that would hold true for TLC. One thing that eqn [2] immediately reveals is that the relationship between the reflected light and the concentration of the chromatographic zone is nonlinear. This is what is found in practice over the full range of concentrations. The data when graphically displayed fit a polynomial curve (eqn [4]).

$$y = a_0 + a_1 \cdot x + a_2 \cdot x^2 \quad [4]$$

However, over a narrow concentration range the relationship is seen to be linear. This means that if it is necessary to have a calibration curve over the whole range of concentrations, at least four but no more than six standards will be required for the determination of one separated analyte. Of course, only two standards may be needed if the concentrations are close to that of the analyte, because it can be assumed that the curve is linear over a small range.

Although it may seem that errors could easily creep into the determination procedure, this is not the case. The assumptions made have only a negligible effect on the final result. Hence, even including any errors which may originate from the scanning spectrodensitometer, the percentage relative standard

deviation is normally below 2% and quite often well below 1%.

For a wide concentration range, the Michaelis-Menten regression curve can be used. The calibration is calculated as a saturation curve:

$$y = \left(\frac{a_1 \cdot x}{a_2 + x} \right) \quad [5]$$

and is theoretically only permitted within the calibration range (between the largest and the smallest standard amounts applied). This regression always passes through the origin.

In some cases there is a better curve fit to the data if the Michaelis-Menten regression does not pass through the origin. Better resolution is therefore obtained if the data produce a function that does not tend towards zero:

$$y = a_0 + \left(\frac{a_1 \cdot x}{a_2 + x} \right) \quad [6]$$

As before, this is theoretically admissible only within the calibration range.

It is also possible to linearize the data graphically. The simplest transformation procedures involve converting the data on reflectance and concentration into reciprocals, logarithms or squared terms. The following equations can thus be proposed:

$$\log R_e = a_0 + a_1 \cdot \log c \quad [7]$$

$$\frac{1}{R_e} = a_0 + a_1 \left(\frac{1}{c} \right) \quad [8]$$

$$R_e^2 = a_0 + a_1 \cdot c \quad [9]$$

where R_e is the reflectance signal and c is the sample concentration.

Eqns [7] and [9] result in linearization over the middle of the concentration range, whereas eqn [8] showed better linearization, but even this fails at very low concentration. None of these methods is able to linearize the data over the whole concentration range.

A solution to the above is to use nonlinear regression analysis based on second-order polynomials. These can be described by the following equations:

$$\ln R_e = a_0 + a_1 \cdot \ln c + a_2 \cdot (\ln c)^2 \quad [10]$$

$$R_e = a_0 + a_1 \cdot c + a_2 \cdot c^2 \quad [11]$$

Over the whole concentration range, eqn [10] gives the best results. In fact, it has been shown that the

data fit is not compromised when as few as three standards are used over the whole concentration range.

The mathematical treatment of the data for fluorescence intensity can be expressed according to the well-known Beer-Lambert law. The fluorescence emission (F) is given by the equation:

$$F = \theta \cdot I_0 (1 - e^{-a_m \cdot l \cdot c}) \quad [12]$$

where F is the fluorescence emission and θ is the quantum yield.

For low sample concentrations the following assumption can be made:

$$e^{-a_m \cdot l \cdot c} = 1 - a_m \cdot l \cdot c \quad [13]$$

Therefore:

$$F = \theta \cdot I_0 \cdot a_m \cdot l \cdot c \quad [14]$$

It follows that, for low concentrations, the fluorescence emission is linearly dependent on the sample concentration. In practice this proves to be the case even though this equation was derived without taking into consideration the influence of absorption or scatter.

Pre-Scanning Considerations

For quantification by reflectance scanning, there is no limitation on the backing used for the chromatographic layer, whether it be glass, aluminium or plastic. However, it must be said that quality of the scanned results, reproducibility and quantitative accuracy mainly depend on the quality of the spot or band application of the sample and the choice of developing solvents. The use of automated spot and band application equipment results in a noticeable improvement in relative standard deviation. In practical terms, band application gives even greater accuracy than spot application. This is to be expected since a scanning slit length on the spectrodensitometer has to be chosen for a spot such that it covers the whole length, as the concentration of the analyte will vary across the spot, with the highest concentration being in the centre. The slit length also has to allow for any variation caused by migration of spots not occurring in a precisely vertical direction (usually due to solvent vapour not being saturated in the developing chamber). For band development, the concentration of the analyte is the same across the length of the band. Hence, there is more latitude on the choice of slit length. Small slit lengths can be chosen which tend to higher sensitivity. Under these conditions with many separations, coefficient of variation (CV) below 1% can be achieved.

Instrumentation

A number of different types of scanning spectrodensitometers are available. Most are now either partially or fully computer-controlled. The parameters such as track length, number of tracks, distance between tracks, slit length and width, scanning wavelength and speed can all be programmed into the computer. Some spectrodensitometers can perform a pre-scanning run to determine the position of maximum absorption for the separated components on the track: this is particularly useful where spot application has been used. After scanning, the spectrodensitometer generates massive amounts of data from all the tracks, including peak height and area and position of zones (start, middle and end), for every component. Usually a chromatogram can be displayed for all tracks. This can be baseline-adjusted and excess noise from the background of the layer can be subtracted. All peaks can be integrated, ready for possible quantification. Although a number of scanning modes are available, such as linear, radial (scanning from the centre for circular chromatograms) and circular scanning around a ring (circular development), by far the most popular is the linear mode, as shown in **Figure 1**.

Normally, three light sources are used in scanning densitometry: a deuterium lamp (190–400 nm), a tungsten halogen lamp (350–800 nm), and a high pressure mercury vapour or xenon lamp for intense line spectra (254–578 nm), usually required for fluorescence determinations.

Three optical methods (**Figure 2**) have been used in the construction of scanning densitometers:

1. single wavelength, single beam
2. single wavelength, double beam
3. dual wavelength, single beam

Construction 1 requires little explanation and is the type manufactured by most commercial TLC companies. Construction 2 divides the single beam into two by means of a beam splitter, so that one half scans over the chromatographic zone whilst the other scans over the background. Both beams are detected by matched photomultipliers and the difference in the signal measured. In construction 3, two wavelengths as close together as possible are chosen, such that fluctuations caused by light scattering at the light-absorbing wavelength are compensated for by subtracting the fluctuations at the different wavelength at which there is no absorption by the chromatographic zone.

In fixed-beam spectrodensitometers, the stage holding the TLC plate under the light beam moves at a constant rate, propelled by stepping motors. Where the light beam moves, it does so in a zigzag fashion over the surface of the stationary plate. Usually the zigzag scanners incorporate a curve linearization technique for absorption measurements. This uses the hyperbolic solution in eqn [2].

Applications

As the chromatogram is permanently or semipermanently held in the layer after development is complete, a number of useful techniques can be used with a scanning spectrodensitometer both to improve the evaluation of the chromatogram and to collect more important data on the separated analytes.

1. The TLC plate can be scanned at a range of different wavelengths. The optimum wavelength can therefore be chosen for maximum absorption of individual sample components. Of course, if two analytes are not completely resolved, but absorb at different wavelengths, then it is possible to quantify the results without further resolution.
2. UV/visible absorption spectra can be obtained for each separated component. Some commercial software then allows the comparison of such spectra with a library of spectra in order to identify unknowns.
3. Spectra can also be obtained for different parts of the chromatographic zone. Hence, spectra can be obtained for the upslope, apex and downslope of the peak to assist the analyst in looking for any peak impurities. Any changes in the spectrum as the light beam traverses the zone would indicate nonhomogeneity.

Figure 2 Scanning modes: (A) single beam; (B) single wavelength, double beam in space; (C) dual wavelength, single beam in time. PM, photomultiplier.

- Background subtraction is another useful feature of most spectrodensitometers. Some background noise will always be present, hence the scanner software can subtract a background scan of the TLC plate before quantification.
- Some instruments can scan and image an entire plate, enabling two-dimensional chromatograms to be evaluated (scan time less than 5 min).
- Forensic: drugs of abuse, poisons, alkaloids, inks
- Clinical: therapeutic drug monitoring, identification of metabolic drug disorders
- Environmental: pesticide residues in crops, crop protection agents in drinking water, industrial hygiene
- Industrial: product uniformity, impurity profile, surfactants, synthetic dyes

The widespread use of planar chromatography means that the applications of spectrodensitometry are almost limitless. Hence, there are extensive publications on the use of scanning densitometry in all types of industry and research. Many of the instrument and plate manufacturers also provide application methods and extensive bibliographies. For example, in all of the following areas scanning densitometry has been used for quantification.

- Biomedical: organic acids, lipids, steroids, carbohydrates, amino acids
- Pharmaceutical: stability and impurities of synthetic drugs, antibiotics, drug monitoring, alkaloids
- Food science: mycotoxins (including aflatoxins), drug residues, antioxidants, preservatives, natural pigments, food colours, spices, flavonoids

To give a flavour of the capability of the technique, the following examples can be considered. **Figure 3** shows the scan obtained from the separation of a number of sulfonamides and antibiotics from a complex animal feed matrix on an HPTLC silica gel plate. Scanning at five different wavelengths allows each of the components to be quantified by measurement at its absorption maximum. The three-dimensional presentation also allows the minor impurities to be more clearly identified. Multi-wavelength scanning is also illustrated in **Figure 4** with an automated multiple development (AMD) separation of pesticides in tap water on HPTLC silica gel plates. **Figure 5** illustrates the fluorescence scan of a range of saturated fatty acids from C₆ to C₂₄, an important food application in fats and vegetable oils. The fatty

acids were derivatized before separation by a unique on-layer technique. The acids are resolved as their dansylcadaverine derivatives on an HPTLC RP18 layer.

The use of spectral identification of an unknown is demonstrated in **Figure 6**. The unknown was eventually identified as morphine, but because ethylmorphine and codeine have such similar spectra (as shown in the overlay), it was necessary to search the spectrum library for the best-fit recorded spectra, and also to check the correlation with the R_F value. This enabled a correlation with morphine of 98.4% to be

obtained for the unknown. This example illustrates the need for the analyst not only to search for the best fit, but also to check the correlation with the R_F value. Had the search been limited to the spectrum library, ethylmorphine could well have been chosen as the unknown.

Video Densitometry

Video densitometry has been developed in the last few years and is now being deployed throughout industry and research. Such instruments use an imag-

ing system consisting of a high resolution CCD camera with a zoom attachment to focus and enlarge the chromatogram, if required and a suitable illumination system. The camera is linked to a computer (usually a PC) and a video printer. The software controls the camera, as well as all parameters such as brightness, contrast, colour balance and intensity. These can be saved for future use or kept as a record of the results. The chromatogram can be presented as an image on the video printer and can be quantified to

obtain the concentration of analytes using the mathematical procedures used in scanning densitometry. As in spectrodensitometric scanning, the software does all the necessary calculations to determine the concentration of analytes. For weakly fluorescing analytes, a small camera aperture (F:22) can be used with long time integration. This enables the imaging of fluorescing compounds which are often invisible to the human eye. The images can be annotated and that annotation stored separately for

readiness in annotating further images. Such images can be stored in a variety of files which can then be used in a number of well-known office programs, such as Word, and PowerPoint.

The illumination system needs a number of features in order to get the best results from the CCD camera unit. Illumination from above is necessary, both visible light and UV light at 254 and 366 nm (depending on the chromatogram). However, it is essential that the light fittings do not interfere with the camera's field of view. Lighting from below the plate can in some cases also prove advantageous in giving a bright image.

Figure 7 illustrates a video print of a separation of corticosteroids developed on an HPTLC silica gel plate. The steroids were detected with blue tetrazolium reagent. Figure 8 shows the scan taken using the software option available. R_F data is recorded in the table below. Figure 9 illustrates a further video print, this time of fluorescent chromatographic zones, photographed under UV light (366 nm). This is a

separation of derivatized saturated fatty acids from C_6 to C_{24} (conditions as in Figure 5).

Although it is possible to quantify results from the video scan, they are not as accurate as those obtained from a spectrodensitometer. Figure 10 and Table 1 show a comparison of the CV for a six-component dye test mixture separated on an HPTLC layer. Whereas the CVs for spectrodensitometric scan are below 2%, those for the video imaging system are typically from 2 to 4%. As most USP (United States Pharmacopoeia) and EP (European Pharmacopoeia) monographs accept CVs of $\pm 6\%$ in most, if not all, cases, the use of video densitometry is acceptable. However, it should be remembered that for fluorescence quenching and absorption measurements below 254 nm, video densitometry will not show any detection. This is one of the present limitations of the technique. Some substances do require shorter wavelength UV light for their detection. In these instances spectrodensitometry is presently the only solution.

Table 1 Comparison of coefficient of variance (CV) with video scanning and spectrodensitometric scanning. Separation of dyes on an HPTLC silica gel plate using toluene as mobile phase

Future Trends

It seems unlikely that video densitometry will ever replace spectrodensitometry as both techniques have unique advantages. On the one hand spectrodensitometry allows the scanning of TLC/HPTLC plates at selectable wavelengths, the acquisition of UV/visible spectra, the determination of peak purity and high accuracy of results. On the other hand, video scanning provides a computer or printed image that can serve as a permanent record of the results obtained which can be documented at any time in a report. Also, for some requirements the accuracy of scanning is sufficient for quantitative evaluation.

With improved software, both densitometric and video scanners are likely to become still more user-friendly. However, more dramatic improvement in the accuracy and reliability of results is more likely to come from the continual improvements taking place in the quality of adsorbents making up the layer. With the introduction of smaller (4 μm) spherical particle sizes, the quality of separation will improve, hence this will be reflected in the scans and quantitative results obtained with both spectrodensitometry and video scanning.

History

Today the term planar chromatography is commonly used as a synonym for high performance thin-layer chromatography (HPLTC) and conventional thin-layer chromatography (TLC). Originally it referred more generally to a family of techniques including TLC, some types of electrophoresis and paper chromatography, which all have in common a stationary phase in the form of a flat thin layer rather than packed into a column. Modern planar chromatography is a form of liquid chromatography and its history is closely linked to the development of chromatography as an analytical tool.

Early roots go back to Beyrinck who in 1889 separated hydrochloric and sulfuric acid by diffusion through a thin layer of gelatine on a glass plate. With the same technique, Wijsman in 1898 was able to demonstrate the presence of two enzymes in malt diastase. When at the end of the 1930s Tswett's column chromatography became successful, research

focused on a faster microchromatographic method, which allowed the exact identification of adsorbed substances. This situation encouraged the transition from a regular column to an open column, a thin layer of adsorbent.

Izmailov and Shraiber are regarded as the inventors of TLC (Table 1). In 1938 they described a method in which microscopic slides were coated with 2 mm layers of a slurry made of chalk, talc, magnesium oxide, lime aluminium oxide or other adsorbents and water. On drying, a thin adsorbent layer was formed. The authors investigated belladonna and other plant extracts by placing a drop of the extract on to the layer. This resulted in the so-called ultra chromatogram that was visualized under ultraviolet light. The chromatogram was then developed with several drops of solvent. The most important advantage of the new method in comparison to column chromatography was the short time of analysis and the low consumption of adsorbents, solvents and samples.

Crowe reported in 1941 the use of a microchromatographic method to select suitable solvents for column chromatography. The procedure was

based on a thin layer of adsorbent poured loosely into a Petri dish.

Meinhard and Hall achieved the first major improvement in layer quality in 1949 with a method called surface chromatography. They used an aqueous slurry of aluminium oxide, Celite and starch coated on microscope slides to produce chromatographic layers free of cracks.

Several years before that, Martin and Synge had taken a different approach while trying to separate amino acids and their derivatives. They developed partition chromatography, in which the stationary phase was coated on to a support such as silica gel and then filled into a column. Solvents such as chloroform were used for elution. In their search for a complementary micromethod, Consden, Gordon and Martin in 1944 used filter paper as an open column, a technique that has its roots in the capillary pictures of Runge (1855) and in the capillary analysis of Schoenbein and Goppelsroeder (1910). Within about 10 years paper chromatography became a universal chromatographic technique.

For the separation of terpenes, Kirchner, Miller and Keller in 1951 improved the surface chromatography technique by incorporating a mixture of zinc silicate and zinc cadmium sulfide as fluorescence indicator into the layer and leaving the Celite out. From various adsorbents to be used on 0.5×5.25 in glass plates called chromatostrips they chose silica gel as the most suitable for their application.

Although employed successfully by many researchers, the thin-layer method was not used widely for several years.

The situation changed with Egon Stahl, who introduced the term thin-layer chromatography in 1956. He realized that the availability of standardized adsorbents of a narrow range of particle size, suitable equipment for preparing thin layers and suitable examples stimulating the use of the method could lead to a breakthrough in acceptance. In 1958 Merck introduced standardized aluminium oxide, kieselguhr and silica gel according to specifications developed by Stahl. Also based on Stahl's ideas, Desaga brought out a basic TLC kit. The wide publicity given to the technique by Merck and Desaga as well as its recognition as a separate chromatographic method by Chemical Abstracts made TLC more and more popular.

In his fundamental book, *Thin Layer Chromatography – A Laboratory Handbook*, published in 1962, Stahl together with several co-authors, made available the results of systematic research on silica gel and other adsorbents, instrumentation and different techniques as well as on the wide applicability of the technique.

The increasing interest in TLC became apparent in a huge number of published papers and several important books, including those by Randerath (1962), Bobbitt (1963) and Kirchner (1967). Due to its much better performance, higher sample capacity and greater flexibility as regards derivatizing reagents, TLC soon replaced paper chromatography in many applications and found entrance to pharmacopoeias as an official method of analysis.

Further developments of planar chromatography were mainly driven by progress in three areas: plate material, instrumentation and theoretical understanding. In 1996 one of the most comprehensive treatises in the field of planar chromatography was published. The *Handbook of Thin Layer Chromatography*, edited by Sherma and Fried, illustrates the current state of the technique.

Plate Material

Experiments with binders were the first step in the improvement of adsorbents that could be made available as pre-coated layers. For reproducible performance, such layers were required to be homogeneous, reliably attached to the support, not affected by solvents and derivatizing agents and universally applicable. Gypsum, which was initially utilized as a binder, failed to yield layers that met the required criteria. Nevertheless, it was still widely used as binder of adsorbents for custom-made TLC plates. In 1965 organic binders based on polyacrylates/methacrylates were introduced which allowed the layer durability and quality to be significantly improved.

Pre-coated plates featuring a wide range of adsorbents, including aluminium oxide, cellulose, polyamide and silica gel as well as a variety of supports such as glass, aluminium or polyester, were introduced to the market. This was a necessary prerequisite for the evolution of planar chromatography into a reliable quantitative technique.

Due to its unsurpassed flexibility and wide applicability, silica gel 60 (average pore size of 60 Å or 6 nm) became the most widely used of all adsorbents.

Paralleling the development in high performance liquid chromatography, an increase in the separation power of TLC plates was expected to result from the utilization of smaller adsorbent particles. In 1975 Merck developed the high performance TLC plate. The main differences of such plates as compared with conventional layers are based on the use of smaller particles with a narrower size distribution. The HPTLC layer is thinner but much more homogeneous and durable than a traditional layer. Separation power and sensitivity are improved and the plates can be used for trace analysis. When introduced to the market these plates became the foundation for instrumental TLC.

A major drawback in the development of layers made with even finer particles to achieve the goal of further improved performance is the restricted capillary flow in such systems. Without suitable forced flow techniques, 3–5 µm seems to be the lower size limit for HPTLC particles.

Partition chromatography on paper was traditionally used to separate hydrophilic substances such as carbohydrates and amino acids. Because these substances are strongly adsorbed on silica gel, reversed-phase techniques had to be employed in order to use TLC. Impregnation known from paper chromatography was used in the 1960s to accomplish this goal. TLC plates were commonly immersed in solutions of alkanes, mineral, silicone or vegetable oils in petroleum ether and then dried. The reversed phase was used with hydrophilic solvents.

When chemically modified silica gel became available, it was attempted to produce true reversed-phase layers for planar chromatography. However, unlike HPLC, which uses a forced solvent flow, TLC has to rely on capillary forces to transport the solvent through the stationary phase. Therefore, reversed-phase materials were developed that retain some of the hydrophilic character of silica gel. Today, a variety of pre-coated reversed-phase plates is available, including RP2, RP8, RP18 and phenyl-modified silica gel. Some of these phases can be used with up to 100% water in the mobile phase. Hydrophilic-modified silica gels originally developed for HPLC also found applications in planar chromatography.

They offer additional selectivity and are less affected by humidity and the gas phase in the developing chamber than silica gel.

Theoretical Foundation

Martin and Synge have chiefly influenced the basic understanding of the fundamentals of chromatography. The significance of their work was acknowledged when both researchers were awarded the Nobel prize in chemistry in 1952. One term defined by Martin and Synge in their theory of chromatography in 1941 was R as the relative rate of movement. LeRosen used a similar term for adsorption chromatography. In 1944 Consden, Martin and Synge named it R_F as the ratio of rate of movement of the adsorbate zone and rate of movement of the developing solvent. Bate-Smith and Westhall defined another important term, R_M , in 1950.

These terms, R_F and R_M , are of fundamental importance for TLC and today many publications deal with the significance of these values. Very early in the development of TLC, Brenner, Niederwieser, Pataki and Weber offered an in-depth presentation of the theory relevant to the principles of TLC as a chapter in Stahl's book. One of the recent and most detailed discussions of all theoretical aspects is found in *Fundamentals of Thin Layer Chromatography* by Geiss, published in 1987. Currently, research into further theoretical understanding of planar chromatography is published in the *Journal of Planar Chromatography*.

An important difference of planar chromatography from column chromatography is the presence of the gas phase. Stahl summarized the effects of chamber saturation on chromatographic separation in 1962. Attempts to control the effects of the gas phase have resulted in a number of special chambers, such as twin trough chamber (CAMAG), BN chamber (Desaga) and horizontal developing chamber (CAMAG). The underlying theories of these devices have been reviewed and compared in detail by Geiss.

In 1940 Trappe introduced the eluotropic series as an arrangement of solvents according to increasing elution strength. Stahl incorporated the concept into one of the first practical approaches to a systematic method development. He linked the three main components of the TLC system – activity of the stationary phase, polarity of the mobile phase and polarity of the sample mixture – in a scheme in which the corners of a triangle point to appropriate combinations that promise successful separations. For example, a lipophilic sample mixture requires a nonpolar mobile phase and a highly active stationary phase, whereas a hydrophilic sample can be separated with

a polar mobile phase on a deactivated stationary phase. Soczewinski mathematically described the effects of the solvent composition on the R_M value in 1969.

In 1971 Snyder published a systematic approach to adsorption chromatography. He related the resolution of the chromatographic system R_s to the selectivity α , the layer quality characterized by the number of theoretical plates N , and the position of the sample in the chromatogram. Because of the fact that for a given separation the TLC plate and its performance are usually constant, resolution can chiefly be improved by changes in the mobile phase. The solvent strength influences the position of the sample in the chromatogram and the solvent properties can change the selectivity of the system. Solvent strength was discussed extensively by Rohrschneider in 1973, while Snyder in 1974 published the so-called selectivity triangle describing proton donor, proton acceptor and dipolar properties of solvents commonly used in chromatography. For HPLC Snyder, Glajch and Kirkland developed a detailed model for solvent optimization in the early 1980s. This model was adapted for use with TLC by Geiss. Nyiredy, Erdelmeyer and Sticher proposed a similar but more empirical approach to solvent optimization in planar chromatography, the so-called Prisma model, in 1985. Because of its simplicity, usefulness and wide applicability the model was readily accepted for method development in TLC.

Recently, models for computer-aided optimization that are more theoretically based have been applied to TLC. They include window diagrams (Wang, 1990), simplex optimizations (Sabate and Thomas, 1984), overlapping resolution maps (Glajch *et al.*, 1980) and cluster analysis (Windhorst *et al.*, 1990).

A useful parameter to characterize the performance of a planar chromatographic system is the separation number, SN, introduced by Kaiser in 1976. In the following years Guichon and Siouffi investigated the relation of SN to height equivalent to one theoretical plate (HETP).

The separation power of planar chromatography is limited due to the capillary flow of the solvent and the resulting limitations in available separation distance. Several attempts have been made to improve performance; One of these is continuous development. The technique, first proposed by Brenner and Niderwieser in 1961, and later by Soczewinski in 1986, is based on the assumption that resolution of planar chromatography can be improved if the solvent is evaporated at the upper edge of the plate, causing continuous development of the chromatogram.

Another approach, multiple development, involves three techniques:

1. Repetitive development with the same solvent in one direction was first theoretically evaluated by Thoma in 1963.
2. Development with one solvent in one direction followed by a second development perpendicular to it with another solvent (two-dimensional TLC) goes back to the work of Consden, Gordon and Martin (1944), who used the technique on paper to separate amino acids. The concept was re-evaluated by Guiochon *et al.* in 1983.
3. Repetitive development with the same solvents in the same direction over increasing distances was introduced by Perry *et al.* in 1975 as a technique called programmed multiple development (PMD). In 1984 Burger modified the technique, in that he developed the plate with solvents of decreasing strength over increasing distances. The term AMD (automated multiple development) distinguishes it from Perry's technique.

The creation of a forced flow through the layer was the third way of improving the performance of planar chromatography. The first experiments to use forced flow in planar chromatography go back to Hopf, who in 1947 invented the Chromatofuge, a device using centrifugal force to accelerate the flow of the mobile phase. Tyihak, Mincsovcics and collaborators introduced another concept, overpressured layer chromatography (OPLC), in 1977. OPLC is of special importance in the development of planar chromatography because it can be regarded as a hybrid between planar and column chromatography, combining the advantages of both techniques.

Instrumentation

The first instruments or tools specifically for TLC that appeared on the market were plate-coating devices, developing chambers derived from paper chromatography tanks and sample application tools.

In the early days of planar chromatography, plate-coating devices played an important role. They allowed the preparation of more or less uniform TLC layers of variable thickness. Besides primitive tools such as glass rods for spreading suspensions of adsorbents, there were two kinds of instruments. In one kind (Desaga, Shandon) a dispensing unit was moved over a series of glass plates. In the other kind (CAMAG), glass plates were moved beneath the dispenser. There have been motorized versions of both types of instruments. Even though some are still on the market today, such devices have lost their importance with the arrival of pre-coated plates in the late 1960s.

In the following paragraphs other instruments are discussed according to their designation: sample

application, chromatogram development and chromatogram evaluation. For a review of today's state-of-the-art instrumentation, refer to the chapter on planar chromatography – instrumentation.

Sample Application

Hand-held micropipettes and microsyringes in connection with application guides were the first devices used for sample application. Some of them can still be found in TLC laboratories. However, it was soon recognized that sample application was the bottleneck with respect to staffing levels in planar chromatography. Until the introduction of HPTLC material with its need for miniaturization, all attempts to rationalize sample application were based on the arrangement of dosage devices in parallel and their simultaneous actuation. The Morgan applicator (1962) used a series of capillaries, which were simultaneously filled and discharged by manual action. A number of automated devices (CAMAG, 1973; Shandon, 1974; Desaga, 1976) used a series of syringes or peristaltic pumps, which delivered the sample solutions controlled by an electric motor. The degree of automation of the various steps, syringe filling, positioning and rinsing varied from device to device.

With the advent of HPTLC, automatic sample application had to be performed sequentially by one dispensing device. The CAMAG Automatic TLC Sampler I (ATS1) was the first instrument of this kind. It was succeeded by the ATS II and finally by the redesigned ATS3, a fully automated device for sample application in the form of spots or bands. Desaga developed a similar instrument the AS30 which works in conjunction with a commercial HPLC autosampler.

Chromatogram Development

Vertical development of one or more plates in rectangular tanks, sometimes covering the stationary phase with a counterplate to form a so-called sandwich, is commonly regarded as the classical technique of planar chromatography. Exclusively, capillary forces drive the mobile phase. However, beginning in the early 1960s, attempts have been made to design chambers for horizontal development (Brenner; Niederwieser-Chamber, Desaga). The Vario-KS chamber (CAMAG) was designed to optimize development conditions. The short bed continuous development (SBCE) chamber was introduced by Perry in 1979 (Regis).

When HPTLC plates, which can only utilize short developing distances, became available, Kaiser developed the U-chamber for circular development (CAMAG, 1976; **Figure 1**). There was considerable interest in the device. Even densitometers that could

Figure 1 (See Colour Plate 29) CAMAG U-chamber (1976) developed by Kaiser.

evaluate circular chromatograms appeared on the market. Kaiser also postulated another developing mode, anticircular, which had other advantages and merits to the circular mode. It is possible that this caused some confusion among potential users of both the new techniques and within a few years the devices disappeared off the market.

Today interest is focused on chambers that allow automated development with reproducible results. One example is CAMAG's automated developing chamber (ADC). Several, mostly experimental instruments have been constructed for OPLC. Today there is still considerable interest in the technique, especially since a modern instrument is on the market (OPLC-NIT, Engineering Company). Another interesting forced flow technique, high pressure planar chromatography, using the circular developing mode and much higher pressure, was proposed by Kaiser. Unfortunately it was never able to grow beyond the experimental stage.

Modern devices using centrifugal forces to generate a forced flow of the mobile phase through the planar bed are the Rotachrom (Petazon) and Chromatotron (Analtech). Both instruments are primarily used for preparative separations.

Densitometric Evaluation

In the 1960s planar chromatograms were evaluated quantitatively with the help of electrophoresis photometers, some of which had to be modified. The major disadvantage of these instruments was the fact that they used visible light and therefore only coloured substances could be measured. This required some sort of visualization technique to be used.

The first densitometers specifically designed for TLC were those by Zeiss (1965), Shoefel (1967), CAMAG (1978) and Shimadzu (1979). These devices

were fitted with a monochromator, utilized ultra-violet light and measured in the reflection mode, which has advantages over the transmission mode.

In 1976 the first experimental set-up for evaluation of planar chromatograms by video technology was described by Devenyi. In the following years instruments originally designed for the evaluation of electrophoresis gels were adapted for use in TLC. TLC-specific video systems have been available since 1988 (Uniscan, Analtech).

Modern scanning densitometers as well as state-of-the-art video densitometry are discussed in the section on Thin-layer (planar) chromatography – instrumentation.

Introduction

At the end of the 1950s thin-layer chromatography was introduced as a rapid, simple technique for qualitative investigations, and it is still widely used in this capacity. With the introduction of high performance plate material (HPTLC) and the availability of dedicated densitometers, thin-layer chromatography has gained increasing acceptance as a quantitative analytical tool. However, to unlock its full potential as an accurate and reliable technique, HPTLC demands the use of instrumentation for the entire process including sample application, chromatogram development and chromatogram evaluation. Since analytical procedures are only as good as their weakest step, additional operations such as *in situ* pre- or post-chromatographic derivatization, as well as sample preparation, require instrumentation for increased reproducibility.

Although several attempts have been made to automate fully the complete TLC process, it seems questionable whether such automation would increase the overall performance of the method. It has proved very difficult to design a device, at a reasonable cost, that

is essentially an automated online system, but at the same time retains the extreme flexibility of the traditional offline design of TLC. One of the many distinct advantages of TLC – the fact that each step can be separated in time and location from all other steps – is very likely to be lost in a fully automated design. Automation of each individual step, perhaps linked by suitable software, appears to be the better choice.

Sample Application

As the first step of planar chromatography, sample application largely determines the overall quality of the separation. All analytes and standards are chromatographed and compared with each other on the same plate, generally by means of migration distance or R_F value. Therefore, exact positioning of the sample during application is crucial for both qualitative and quantitative TLC. Quantitative work also requires exact reproducibility of applied volumes. Furthermore, in order to utilize fully the separation power of the layer, it is important to restrict the dimension of the sample origin in the direction of chromatography. The advantage of instrumentation is mainly derived from a much higher reproducibility of all these parameters.

Generally, two principal sample application techniques are distinguished: application of spots and application of bands. The selection of a sample

application technique depends on factors such as the nature of the analytical task, the type of sample matrix, workload and time constraints, the type of separation layer, and the sample volumes to be applied.

Sample volumes that can be applied as spots delivered in one stroke are 0.5–5 μL on conventional layers and 0.1–1 μL on HPTLC layers. Larger volumes may be applied either as spots by using a device with controllable delivery speed, or by spraying them on in the form of narrow bands.

Sample Application as Spots

The simplest technique to apply samples as spots is to use a fixed volume pipette that fills by capillary action and delivers its content when it touches the layer. Variable volumes can be applied with a syringe, preferably one with micrometer control. Instruments for sample application should ensure two things: first, that the spots are precisely positioned and second, that the layer is not damaged during application. The Camag Nanomat is a mechanized spotting device using fixed volume glass capillaries, which are lowered onto the layer with reproducible contact pressure (Figure 1). The exact position of the spot is mechanically controlled. An instrument designed for the use of microlitre syringes is the Desaga PS 01 Sample Applicator.

Sample Application as Bands

Sample application in the form of narrow bands provides the highest resolution attainable with a given chromatographic separation method. The sample is typically contained in a syringe, which is emptied by a motor. Delivery speed and volume are electronically controlled. A stream of an inert gas such as nitrogen

Figure 1 Camag Nanomat.

Figure 2 Camag Linomat IV.

around the tip of the syringe atomizes the sample and creates a band on the TLC plate if either the syringe or the plate is moving linearly. Because large sample volumes can be applied, this technique is able to lower dramatically the determination limits with respect to analyte concentration in the sample solution, e.g. in trace analysis. Another benefit of the spray-on technique for quantitative analysis is the possibility of applying different volumes of the same calibration standard instead of equal volumes of different standard concentrations. The spray-on technique also allows unknowns to be simply over-sprayed with 'spiking' solutions for the standard-addition method.

The Linomat (Figure 2) allows sample application in narrow bands of variable length by a multipassage spray-on technique. The instrument can be used to apply sample volumes of 2–100 μL onto HPTLC plates or conventional layers. By employing the Linomat spray-on technique, the gain in precision of quantitative TLC analysis can be expected to be in the range of 30%, i.e. from 1.5% relative standard deviation to 1.0%, provided that chromatographic resolution is not a problem. If samples are complex, 'dirty', tend to tailing, or are otherwise 'difficult', the choice between band application and spot application may determine whether or not a meaningful quantitative result will be obtained at all.

Automated Sample Application

Sample application in quantitative TLC analysis can take up as much as one third of the time needed for the entire analysis. When carried out manually, this is pure labour time. Therefore, attempts to automate or otherwise rationalize this step have been made since the early days of TLC.

Devices using a series of capillaries or syringes were employed with partial success in conventional TLC.

However, none of the multicapillary or multisyringe devices were truly suitable for the smaller dimensions of HPTLC. Applying samples sequentially proved to be a more appropriate approach to solving the problem of automated sample application without sacrificing precision.

The Camag Automatic TLC Sampler III is a flexible computer-controlled device that can apply samples automatically from a rack of sample vials. The samples are transferred from the vials onto the plate with a steel capillary either as spots by contact or as bands using a multipassage spray-on technique. The sample-dispensing speed, sample volumes and application pattern are freely selectable. Each application step is followed by a programmable rinsing cycle to avoid cross-contamination of samples. Because the software of the instrument is compatible with the software for densitometric chromatogram evaluation, all calibration data need to be entered only once. Another advantage of this automated system is its Good Laboratory Practice/Good Manufacturing Practice (GLP/GMP) compliance.

The Desaga TLC Applicator AS 30 also applies samples to a planar chromatography surface in the form of spots or bands. The differences between the two applicators are that spots are applied by spraying and that a one-passage spray-on process produces bands. The AS 30 Applicator can be coupled with a typical HPLC autosampler. The functionality of such a combination is comparable to that of the ATS III.

Chromatogram Development

Although chromatogram development is the most decisive step in the TLC procedure, important parameters are often not given the attention they deserve. Even as part of quantitative analytical procedures, most planar chromatograms are still developed with rather primitive equipment.

The classical way to develop a planar chromatogram is to place the plate with its lower edge immersed in the developing solvent contained in a tank. While the solvent ascends the plate, the layer interacts with the vapour phase in the tank. Since developing tanks of different manufacturers vary considerably in size, chromatograms developed in one device cannot generally be duplicated in another. It is customary to line the inside of the tank with filter paper soaked with the developing solvent. Although this can be often advantageous, it is not always the case.

A counter plate arranged at a small distance opposite to the layer can largely suppress interaction between the dry or wetted layer and the gas phase. This is called a 'sandwich configuration'. Although sandwich chambers tend to improve the reproducibility of

the separation, secondary fronts, caused by partial solvent de-mixing of complex mobile phases, are often produced and may interfere with resolution of samples.

A limited degree of influence over the gas phase parameters during chromatographic development is offered by the twin-trough chamber. A special advantage of this chamber is the possibility of affecting the separation through preconditioning.

The horizontal developing chamber (HDC; Figure 3) allows a planar chromatogram to be developed in both the sandwich and tank configuration with or without solvent vapour saturation. For development in the HDC, samples can be applied parallel to both opposing edges of the plate, which is then developed from both sides towards the middle. In this way the number of samples per plate can be doubled. However, when used for one-directional development, the HDC also offers advantages in that chromatographic conditions can be standardized. This type of chamber uses very small amounts of developing solvent (2×5 mL for a $20 \text{ cm} \times 10 \text{ cm}$ plate) and offers, therefore, an economical alternative to the conventional developing tank.

Automatic Chromatogram Development

The automatic developing chamber (ADC) provides instrumental control of the classical one-step isocratic chromatogram development. Preconditioning, tank or sandwich configuration, solvent migration distance, and the drying conditions can be preselected and are automatically maintained to ensure high reproducibility of the chromatographic result.

Figure 3 Camag horizontal development chambers.

Computer-Controlled Multiple Development of Planar Chromatograms

Automated multiple development, more particularly when performed as a gradient technique, achieves the maximum resolution feasible within the limited separation distance available on a HPTLC plate. In terms of peak capacity it compares with HPLC while retaining the inherent benefits of planar chromatography. The automated multiple developing system (AMD; Figure 4) serves for this type of chromatogram development. A step gradient of decreasing eluotropic strength and changing selectivity is created and each development proceeds to a higher migration distance than the one before. A typical standard gradient changes the developing solvent from methanol to dichloromethane to hexane in 25 steps over a final migration distance of 65 mm. Between each step the plate is dried under vacuum. The software allows the composition of developing solvent to be specified as well as the developing distance for each step. Solvent volumes are measured with syringes and migration distance of the solvent front is measured with sensors. Preconditioning through the gas phase prior to development is possible.

Forced Flow Layer Chromatography

Several attempts have been made to accelerate the solvent flow in planar chromatography. Applying pressure in the linear or radial direction or using

centrifugal forces have been described. The only technique that has survived is the so-called 'over-pressure layer chromatography' (OPLC), which is described in detail elsewhere in this volume.

Densitometric Chromatogram Evaluation

Principle

During densitometric evaluation of a planar chromatogram, its separation tracks are scanned with a light beam in the form of a slit adjustable in length and width. The photosensor of the densitometer measures diffusely reflected light. The difference between the optical signal from the sample-free background and that from a sample zone (fraction) is correlated with the amount of the respective fractions of calibration standards chromatographed on the same plate. Densitometric measurements of planar chromatograms can be made by absorbance or by fluorescence.

As an alternative to classical densitometry, a planar chromatogram can be evaluated by video technology.

Comparison of Video Technology with Classical Densitometry

Classical densitometry uses the spectral range from 190 to 800 nm with high spectral selectivity. Absorption spectra for substance identification can be recorded within this whole span. In contrast, video technology functions only in the visible range. The UV region – exceptionally productive for planar chromatography – is only indirectly accessible through the use of an UV indicator embedded in the layer and in cases where samples fluoresce. In this respect video technology parallels the human eye.

Spectral selectivity, a strong point of the classical densitometer, is not accessible with a video system. The greater the absorbance of the analyte at or near the excitation maximum of the UV indicator (254 nm), the higher are the sensitivity and accuracy of video quantification. In certain cases they may even become comparable to those of classical densitometry.

In fluorescence mode video and classical densitometry are comparable in respect to detection of emissions in the visible region, caused by long-wave UV light (366 nm). However, video technology lacks the variable-excitation-based selectivity of classical densitometry.

The limitation of image processing to visible light is not caused by the video camera, but by the fact that no solution has yet been found for uniformly illuminating a plate with monochromatic light of a selected

Figure 4 (See Colour Plate 30) Camag automated multiple development chamber AMD 2.

wavelength. *In situ* spectroscopy is only possible with the classical densitometer.

Features of a Modern Chromatography Densitometer

The Camag TLC Scanner 3 may be used to illustrate typical features of a modern densitometer (see Figure 5). Some particulars of other densitometers are also discussed. Technical data for a number of densitometers are given in Table 1.

Two continuum lamps, a deuterium and a tungsten-halogen lamp, in combination with a monochromator generate light of 5–20 nm bandwidths in the spectral range from 190–800 nm. A third, high pressure mercury vapour lamp provides high energy for scanning by fluorescence. The lamps are selected and positioned automatically. Plates up to 20 cm × 20 cm are placed on a stage that is mechanically operated in the *x*- and *y*-directions. The scanning speed is variable to a max of 100 mm s⁻¹. Several cutoff filters can be selected for fluorescence scanning.

All functions of the scanner as well as generation and processing of data are controlled by a personal computer using dedicated software. A typical sequence of quantitative evaluation of a chromatogram includes raw data acquisition, data integration, calibration and calculation of results, and generation of the analysis report.

Raw data are sampled by scanning the chromatogram plate in the direction of chromatography, track by track. Integration is performed from the raw data after all the tracks on a plate have been measured. The system automatically defines and corrects the baseline and sets fraction limits. The operator can accept these or can override the automatic process by manual integration.

In the calibration routine, peak data of the unknowns are related to those of the calibration standards. From several calibration functions, including single- or multi-level with linear or polynomial regression, the most suitable for the task is chosen.

The software automatically stores and retrieves all data files and generates a report containing the date

and time of the last change, plus a unique system-generated identification number for GMP/GLP recognition.

Modern scanners are usually able to do more than just quantify the substances on a plate. The following is a selection of other capabilities.

Multiwavelength scanning This expression is often misinterpreted as scanning at selectable wavelengths, a very basic feature of any densitometer fitted with a monochromator. Multiwavelength scanning means that initially acquired raw data of up to ten different wavelengths can be separately processed post-run in the integration and calibration routine. Therefore, each substance can be quantified at the wavelength of its maximum absorbance (see **Figure 6**). Dual-wavelength scanning, which may be used for example to eliminate matrix effects, is a simple variation of multiwavelength scanning.

Recording *in situ* spectra Absorption spectra across the entire range of the monochromator can be measured and, within certain restrictions, so can fluorescence excitation spectra. In the Camag scanner both deuterium and halogen–tungsten lamps remain powered the whole time and are therefore well stabilized. The spectral data can be processed post-run for various purposes:

- to determine the optimum wavelength(s) for quantitative scanning;
- to identify individual fractions by comparison with spectra of authentic standards co-chromatographed on the same plate or stored in a spectrum library;
- to check identity by superimposing the spectra of all fractions within the same R_F window;
- to check the purity of fractions by superimposing the spectra from different positions within a spot.

Scanner validation Automatic instrument validation is available as an option of the software. In the scanner validation procedure the following checks are performed: wavelength adjustment of the monochromator, correct stage positioning; condition and alignment of lamps, condition and alignment of the optical system; and functioning of the electronics. The results, together with the target values, are printed as a validation report.

Features offered by TLC densitometers Instead of scanning a chromatogram track with a fixed slit, it is possible to move a light spot in a zigzag or meander form over the sample zones, whereby the swing corresponds to the length of the slit. This feature, offered by the Desaga CD 60 densitometer and also by the Shimadzu CS 9000 series scanner, is claimed to correct chromatogram distortions. Disadvantages are the lower spatial resolution, particularly in the case of

Figure 6 (See Colour Plate 31) Multiwavelength scan of a pesticide mixture after AMD separation.

HPTLC separation material, and unfavourable error propagation, when data of sampling points from different positions are averaged.

Chromatogram Evaluation with Video Technology

A video imaging system typically consists of a lighting module such as Reprostar 3 featuring short-wave UV, long-wave UV and visible light, a charge-coupled device (CCD) camera with zoom objective, computer with frame grabber, and imaging and evaluation software such as VideoStore/VideoScan). Most software allows the user to annotate and manipulate the images. VideoStore image data are archived under observation of GMP/GLP. They can be retrieved any time for quantification with the VideoScan software. Multiple images can be opened and their analogue curves can be compared.

The benefits of chromatogram evaluation by video technology are speed, easy and intuitive operation, and the fact that saved chromatograms can be evaluated at any time if required.

Post-Chromatographic Derivatization

It is an inherent advantage of planar chromatography that fractions are stored on the plate and can readily be derivatized after chromatography in order to render them detectable, to improve detection limit, or to change selectively properties of sample components.

Liquid derivatizing agents can be transferred onto the plate by spraying or dipping. Provided the reagent is suitable, dipping is the preferred technique.

The Chromatogram Immersion device by Camag is an example of an instrument that allows proper execution of the dipping technique. The chromatographic plate must be immersed and withdrawn at a uniform speed to avoid tide marks, which could interfere with densitometric evaluation. By maintaining a defined immersion time, derivatization conditions can be standardized.

Spraying has to be used when two reagent solutions have to be applied in sequence without intermediate drying. Diazotization followed by coupling is an example. There are several sprayers on the market, from simple laboratory atomizer to electropneumatic TLC sprayers.

Whenever reagents are sprayed onto a plate, an efficient dust and mist-removing device should be used to protect laboratory personnel against poisonous or irritating sprays and solvent vapours. Commercial equipment ensures the complete removal of excess spray from the atomizer and spray particles rebounding from the TLC plate. There is no deflection of the spray jet before it reaches the chromatogram, an effect often occurring in a normal laboratory fume hood.

In most cases, the derivatization reaction needs to be completed by heat treatment. Heating the

chromatogram plate uniformly and reproducibly at the desired temperature can be accomplished with a heater specifically designed for this purpose.

Combination of Planar Chromatography with Other Techniques

Combination of planar chromatography and various chromatographic or non-chromatographic methods has been reported frequently. Such combinations include HPLC-TLC, TLC-FTIR, TLC-Raman, TLC-SERS and TLC-MS. Most devices to effect these combinations have been custom-built and only a few are commercially available.

Coupling HPLC with Planar Chromatography

Combining separation techniques that utilize different mechanisms to a multidimensional approach increases the potential of the individual techniques by an order of magnitude. HPLC in reversed-phase mode is one of the most powerful separation techniques available for nonvolatile substances. Online coupling of HPLC with a multiple development system using normal-phase chromatography results in peak capacities of around 500.

A device for mass transfer from HPLC to planar chromatography consists of a sample spray-on device that is connected to the column outlet. Since the maximum quantity of liquid that can be sprayed on a silica layer without washing it away is limited to $10\text{--}60\ \mu\text{L min}^{-1}$, depending on the mobile phase, a microbore HPLC unit is the most appropriate for this technique.

FTIR Evaluation of Planar Chromatograms

The combination of planar chromatography with Fourier transform infrared *in situ* evaluation is a useful method for the identification of complex mixtures and their constituents. Although determination limits ($1\text{--}10\ \mu\text{g}$ per fraction) are higher than those for *in situ* UV spectroscopy, the method can be used for the quantification of substances that exhibit no suitable UV response and are not amenable to derivatization. A major drawback of *in situ* FTIR is the strong absorption of silica gel between $3700\text{--}3100$ and $1650\text{--}800\ \text{cm}^{-1}$. Spectral correction can be achieved by background subtraction of data recorded from an empty track.

Combination of Planar Chromatography with Raman Spectroscopy

Regular Raman spectroscopy as well as the SERS technique (surface enhanced Raman scattering) is

suitable for the identification of substances on a TLC plate. *In situ* Raman generates spectra that are more or less identical with published Raman spectra measured on solids. Detection limits are comparatively poor, i.e. in the range of $0.5\text{--}5\ \mu\text{g}$ per fraction. SERS is suitable for detection and identification of compounds in the picogram range, if the layer is treated with a colloidal silver solution. The user must record a custom library of SERS spectra from a similar layer in order to perform an identification of a totally unknown material.

A multidimensional combination of outstanding separation power is that of HPLC coupled with automated multiple development planar chromatography featuring evaluation by a special SERS technique employing silver deposition via the gas phase.

Combination of Planar Chromatography with Mass Spectrometry (MS)

For the *in situ* identification of compounds separated on a TLC plate, molecules must be desorbed from the layer and then introduced into the ion source of the mass spectrometer. Such desorption can be accomplished by laser ablation or particle beam sputtering techniques. Ionization methods include conventional chemical ionization (CI), fast atom bombardment (FAB), liquid secondary-ion mass spectrometry (liquid-SIMS), and matrix-assisted laser desorption/ionization (MALDI). Mass analysers are either sector field, quadrupole or time of flight (TOF) instruments. The principal limitation of the interesting TLC-MS hyphenation is that there is no MS instrument available that takes $10\ \text{cm} \times 10\ \text{cm}$ or larger plates.

Future Trends

Future developments of instrumentation are likely to focus on improvement of the speed and flexibility of all automated individual steps. The future will see systems that combine the automated steps – sample application, chromatogram development and evaluation by video technology – and have the option to interrupt the process where desired and to interpose additional or alternative steps. Software for control and documentation of all steps of the TLC procedure will be in full GLP/GMP compliance. Other expected developments will be in the area of commercially available interfaces for hyphenated techniques and improved separation media, e.g. spherical material. All this will improve the recognition and acceptance of planar chromatography as a reliable, cost-effective and environmentally friendly method of analysis complementing other chromatographic techniques.

Ion Pair Thin-Layer (Planar) Chromatography

Introduction

The separation of polar, ionizable substances can cause problems for simple partition- or adsorption-based chromatographic systems and this is as true in thin-layer, or planar, chromatography (TLC) as for any of the other liquid chromatographic techniques. Often the problem can be dealt with by the simple expedient of controlling the pH of the solvent used for chromatography, in order to suppress the ionization of the solute and thereby reduce its polarity. However, with very polar compounds this is not always a successful strategy and in such circumstances it may be more practical to employ an ion pair (IP) reagent (often referred to as soap chromatography in the early literature). A further benefit of using such an approach is that a hydrophobic IP reagent may, in addition to masking the ionizable group, usefully modify the overall polarity of the complex and thus cause a dramatic change in chromatographic properties. Whilst IP-TLC has not been as widely employed as IP-high performance liquid chromatography (IP-HPLC: described elsewhere in this encyclopedia), there have been sufficient examples of the technique to demonstrate its utility for both acids and bases.

In addition to simply using IP reagents in order to obtain suitable chromatographic separations for substances that are too polar to chromatograph in any other way, this type of TLC has other uses. For example, faced with a mixture of neutral and ionizable compounds, an IP reagent may enable the ana-

lyst to introduce additional selectivity into the system. This can enable the R_F of more acidic or basic compounds to be altered whilst leaving those of neutral solutes unchanged and thereby effecting a separation. The addition of an IP reagent to a system can also provide a rapid indication of which compounds in a mixture are ionizable. There have also been several examples of the use of chiral IP reagents for the separation of enantiomers.

The scope and practice of IP-TLC are described below.

Practical Aspects of IP-TLC

Suitable Ion Pair Reagents for IP-TLC

A range of IP reagents have been used for TLC and high performance TLC (HPTLC). These include both the conventional IP reagents used in other forms of liquid chromatography, such as heptanesulfonic acid, triethanolamine dodecylbenzene sulfonate and sodium dodecyl sulfate for bases and quaternary ammonium salts including tetramethyl, tetrabutylammonium and cetrimide for acids. Some limited work has been performed using 'bolaform' bisquaternary ammonium compounds where two such groups are separated by an alkyl chain of varying length which acts as a spacer.

In addition to these IP reagents, it is arguable that in cases where strong organic acids such as trifluoroacetic acid have been used to enable good chromatography of bases to be obtained, a form of IP chromatography is being performed.

Chiral IP reagents have been employed in a limited number of cases (see below) in order to effect the resolution of certain basic drugs.

Methods for the Use of IP Reagents

When attempting to perform IP-TLC it is worth noting that there are several methods of using the reagents. The best results depend to no small degree on the nature of the reagent and the stationary phases employed. Thus the reagents can be included as additives to the solvent system, can be applied to the plates via impregnation with a suitable concentration of the reagent in a volatile solvent prior to chromatography, or a combination of inclusion in the mobile phase and impregnation. Thus, in the case of small, polar IP reagents such as the quaternary tetramethylammonium salts, inclusion in the mobile phase is essential if chromatography is being attempted on a bonded-silica stationary phase. This is because the reagent is so polar that it is not retained on the stationary phase but migrates with the solvent front. The reagent is thus rapidly removed from the analytes with which the ion pairing is desired, with the result that there is little effect on chromatography. In contrast, any attempt to use the combination of a long chain IP reagent such as sodium dodecyl sulfate or cetrinide as a mobile-phase additive in combination with a bonded phase will invariably be met with disappointing results. This is a direct result of the strong interaction of the nonhydrophilic side chain with the stationary phase, which results in the slow migration of the reagent (if it migrates at all) compared to the solvent. Thus, by the time the advancing solvent front reaches the spots corresponding to the analytes, the concentrations of IP reagent are negligible and no real effect on the subsequent chromatography is seen. For such reagents the prechromatographic impregnation of the stationary phase is essential.

Some of these effects, which illustrate the importance of the correct use of the reagent, are shown in **Figure 1** for a number of dihydroxybenzoic acids with C_2 -bonded HPTLC plates when the quaternary ammonium IP reagent tetrabutylammonium bromide was used. Using the reagent in the mobile phase alone gave unsatisfactory results: there was either little effect or the production of double spots (for ion-paired and nonpaired solute; **Figure 1A**). When the C_2 phase was impregnated with the reagent prior to chromatography, much better results were obtained (**Figure 1B**); maximum effects were seen when the reagent was impregnated into the stationary phase and included in the solvent (**Figure 1C**). Postchromatography, the zones of the plate where the reagent was present were located, due to the lack of a suitable chromophore, using iodine vapour. This provides a simple, rapid and effective method for determining the location of these reagents. This can be important in troubleshooting a separation where the effects obtained are not those anticipated.

The impregnation procedure used can affect the final result and detailed studies have been undertaken to optimize this step. For example, if a paraffin-impregnated silica gel TLC plate is to be used with an IP reagent, there would be an obvious benefit to performing paraffin and IP impregnation with a single solution. However, it has been shown that dipping the plate in paraffin followed by the IP reagent solution results in a much higher quantity of IP reagent being adsorbed than the simultaneous application of paraffin and reagent.

Concentration Effects

In our experience, one of the most important factors in making IP-TLC effective is the concentration of the

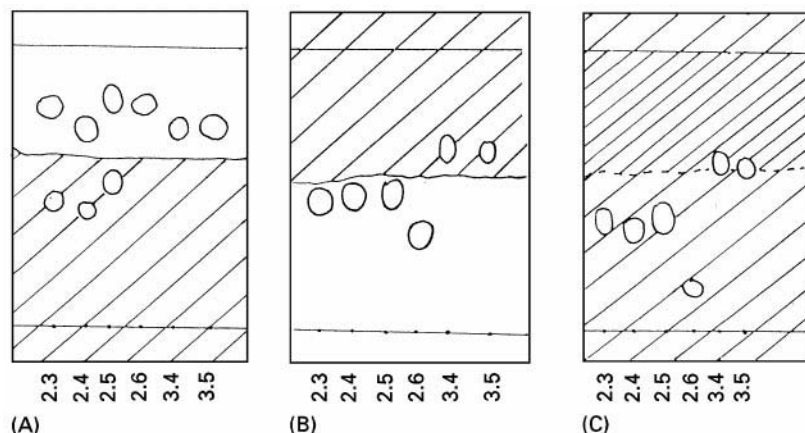

Figure 1 The distribution of IP reagent (tetrabutylammonium bromide) following chromatography as detected using iodine vapour. Shaded areas show the highest concentrations of iodine and thus ion-pair reagent. 2.3, 2.4, 2.5, 2.6, 3.4 and 3.5 are the dihydroxybenzoic acids used as model compounds.

Figure 2 Effect of the concentration of tetrabutylammonium bromide used to impregnate C₂-bonded reversed-phase TLC plates on the R_F values of a range of dihydroxybenzoic acids.

reagent employed. This is shown in Figure 2 for the reagent tetrabutyl ammonium bromide used for a range of dihydroxybenzoic acids on C₂-bonded reversed-phase (RP)-TLC plates. As this figure shows, with methanol–water (1 : 1 v/v) as mobile phase when no reagent is present the test compounds all have R_F values in the range 0.8–0.9. Prechromatographic impregnation of the phase with a solution of the reagent in dichloromethane–ethanol (85 : 15 v/v) at 0.001 mol L⁻¹ was virtually without effect. However, increasing the concentration of the impregnating solution to 0.05, 0.01, 0.5 and 0.1 mol L⁻¹ produced significant reductions in R_F that increased with increasing reagent concentration. Above 0.01 mol L⁻¹ the reduction in R_F observed does not dramatically increase with increasing concentration.

The Role of pH

In IP chromatography in HPLC, the careful control of pH is probably the single most important factor in obtaining retention and ensuring reproducible results. Surprisingly, this is not always the case in IP-TLC and pH effects are often of only marginal significance. In general, with IP reagents such as tetrabutylammonium salts, effects of pH are not observed at all over the range 2–10 (Figure 3). For effects over the range 2–4, there is a gradual decline on silica gel and paraffin-coated silica gel plates and a general decline in R_F is observed with increasing pH on C₁₈-bonded phases (Figure 4). Some of these differences in behaviour between IP reagents may be explained in terms of the way in which the reagents interact with the sta-

tionary phases. A working hypothesis that has been advanced is that on silica gel a reagent such as cetrimide is likely to bond ionically to the acidic surface silanols to form a hydrophobic layer in which the hydrophobic alkyl chains of further cetrimide molecules can sit. As long as the silanols on the silica surface remain ionized this would effectively make a relatively stable ion exchange phase (Figure 5). However, as the pH is lowered, such interactions become less favoured and the layer breaks down with a consequent rapid increase in the R_F of polar solutes. IP reagents such as the tetramethyl- or tetrabutylammonium compounds, which have very different physicochemical properties to cetrimide, would seem at first glance to be much less likely to form this type of ordered layer structure, and so the effect of solvent pH on the surface silanols of the stationary phase would be likely to be less important. Whatever the cause, the susceptibility of IP-TLC to pH effects seems to require the presence of a long aliphatic chain as they are only observed with quaternary ammonium trimethyl-*N*-alkyl IP reagents of C₈ or longer.

It may be advantageous under some circumstances to be able to choose between IP systems that are to all intents and purposes insensitive to solvent pH and those with which pH may be used as another parameter with which to manipulate the separation.

Stationary Phases for IP-TLC

A range of stationary phases have been used for IP-TLC including silica gel, paraffin-coated silica gel

Figure 3 Lack of effect of pH on the R_f values of some dihydroxybenzoic acids on IP-TLC using tetrabutylammonium reagents on (A) paraffin-coated silica gel TLC plates and (B) C_{18} -bonded TLC plates. ■, gentisic acid; ●, 2,5-dihydroxybenzoic acid; ○, 2,6-dihydroxybenzoic acid; ▲, salicylic acid.

and a range from C_2 , C_8 , cyanopropyl, aminopropyl, diphenyl to C_{18} -bonded layers. Chromatography of polar ionic analytes can be obtained with a range of IP reagents on silica gel, paraffin-coated silica gel, alkyl-bonded (C_2 to C_{18}) and diphenyl-bonded layers. However, it is our experience that aminopropyl layers give poor results with IP reagents, and that spot shapes on cyanopropyl layers are poor. It should be noted that these comments are based on limited studies and relatively little work has been done to investigate the use of some of these layers (e.g. cyanopropyl, aminopropyl and diphenyl). It should also be noted that not all reagents can be used with all phases. For example, tetrabutylammonium bromide can be employed with alkyl-bonded stationary phases or paraffin-coated silica gel, but is ineffective on bare silica. In

contrast, cetrимide works well on both bonded stationary phases and silica gel.

Quaternary Ammonium IP Reagents for the TLC of Acids

Reverse-phase IP-TLC In general, the TLC of weakly acidic compounds (e.g. nonsteroidal anti-inflammatory drugs such as ibuprofen or naproxen) can be performed on C_{18} -bonded layers without the need for ion pairing, or indeed for the need for an acidic mobile phase to control the ionization of the analytes. This contrasts with the experience of obtaining satisfactory retention in HPLC for such compounds, but this merely serves to reinforce the fact that the important factors governing retention in RP-TLC and RP-HPLC are not necessarily the same. This may perhaps

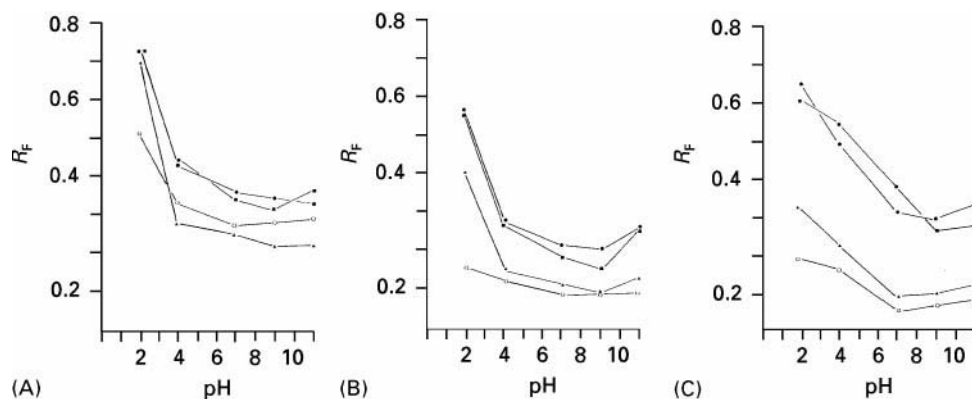

Figure 4 Effect of pH on the R_f values of some dihydroxybenzoic acids on (A) silica gel coated with cetrимide, (B) paraffin-coated silica gel and cetrимide and (C) C_{18} -bonded silica gel and cetrимide.

Figure 5 A schematic representation of the possible interaction of long chain IP-reagents with silica gel.

be a result of the acidic nature of the silica surface remaining after the bonding process: this may suppress the ionization of these weak organic acids. This is not to say that IP reagents have no effect on the TLC of such compounds – far from it – and IP reagents can be used to modify R_F for these analytes if required. However, in the case of the RP-TLC of strongly acidic compounds, there is no doubt that the chromatography of such analytes greatly benefits from the use of an IP reagent (and may not be possible without them). Examples of the type of compound where significantly better results are obtained with the employment of an IP reagent (either in terms of ability to modulate R_F or improvements in spot shape) include substances such as mono- and dihydroxylated benzoic acids (e.g. salicylic acid, gentisic acid, etc.). Suitable reagents for the IP-TLC of acidic compounds include tetramethylammonium and tetrabutylammonium salts, cetrimide and the bola-form IP reagents alluded to above.

Acidic IP Reagents for the TLC of Bases

A number of applications of the use of IP-TLC for the chromatography of bases have also been described. That said, it is our experience that the TLC (both normal-phase (NP) and RP) basic compounds can often be performed without recourse to IP systems. Thus, the inclusion of ammonia in NP-TLC systems is often enough to suppress the ionization of weak bases and obtain good chromatography. In RP systems the main problem is usually spot tailing, as the basic analyte interacts with the residual silanols present on

the silica surface. This effect can usually be controlled by using a competing base such as ammonia or triethylamine in the eluent. Alternatively a strong organic acid, such as trifluoroacetic acid (TFA), can be used as a mobile-phase additive (0.1% v/v). It is arguable that this is in fact an ion pairing effect and that the TFA is forming an IP with the basic group on the analyte, thus preventing silanophilic interactions. In HPLC the IP chromatography of bases is usually effected using sulfonic acids such as heptanesulfonic acid and the longer chain dodecylsulfate. Studies have been performed with these reagents on silica gel, silanized silica gel, paraffin-coated silica gel and a range of C_{18} -bonded phases, with the best results usually obtained by coating the reagents on to the plate rather than including them in the mobile phase.

In an early study silanized silica gel was used and the reagents (sodium lauryl ethersulfate or triethanolamine dodecylbenzenesulfonate) were mixed with the stationary phase prior to the preparation of the plates. The amount of reagent employed varied from 0.025% up to 4%, with the maximum effect on the R_F of the test amines seen between 2 and 3%. Later studies showed that a range of reagents, from methyl up to dodecyl sulfonic acids, could be employed with C_{18} -bonded plates and acetone–water (0.1 mol L⁻¹ IP reagent) solvent system for the IP-TLC of analytes such as atropine, codeine, eupaverin and papaverine. Not surprisingly, the authors found that the trend for decreasing R_F of the test solutes was correlated with increasing alkyl chain length for the reagent.

In our own studies the IP-TLC of β -blockers was investigated using silica gel, paraffin-coated silica gel

or C_{18} plates impregnated with sodium dodecyl sulfate. In fact it was possible to obtain good results for these analytes only on the C_{18} -bonded materials. The largest effects on chromatographic behaviour were seen for the dodecyl sulfate reagent.

Overpressure IP-TLC Overpressure TLC (described in detail elsewhere in this Encyclopedia) is a forced flow planar chromatography system whereby the TLC plate is held under pressure beneath an inert and impermeable membrane and the mobile phase is pumped through the layer. This mode of TLC has been used successfully with quaternary ammonium IP reagents using both silica gel and bonded stationary phases and with 10-camphor sulfonic acid on silica gel. When using a reagent such as cetrimide the results were shown to be only really acceptable if the plates were precoated with the reagent, at a concentration of 0.05 mol dm^{-3} . However, if in addition to coating the plates, cetrimide (optimally 0.1 mol dm^{-3}) was also included in the developing solvent, a noticeable improvement in spot shape was seen. Interestingly, and unlike the situation observed for normal IP-TLC, a noticeable dependence of R_F on pH was noted: best results depended upon the stationary phase. So, with bare silica pH 5 gave the best separations whilst on a C_{18} -bonded silica pH 8 was optimal. Later work extended the use of IP-overpressured liquid chromatography (IP-OPLC) to basic compounds with 10-camphor sulfonic acid as the IP reagent, with silica gel as the stationary phase. Interestingly, the investigators noted that this reagent was ineffective when used alone (impregnated into the silica gel by immersion, with or without the reagent also present in the solvent). However, when the plates had previously been impregnated with cetrimide, good results were obtained. This was interpreted as the formation of a double layer of some description. Presumably the cetrimide interacts with the silanols on the surface of the silica gel to form a lipophilic layer on to which the camphor sulfonic acid can be adsorbed. Optimum results are obtained if the plates are pretreated with 0.05 mol L^{-1} solutions of the reagents and both cetrimide and 10-camphor sulfonic acid are present in the eluent at the same concentration. pH effects were also noted in this work, with the best results seen at pH 5.5.

Chiral IP-TLC IP reagents have been used in a limited number of cases in HPLC for the resolution of enantiomers and similar work has also been performed in TLC. Here the aim is to form diastereoisomeric complexes with different chromatographic mobilities rather than mask polar ionizable groups in order to moderate polarity. A number

of IP methods for β -blockers such as propranolol and alprenolol have been reported, based on the use of *N*-benoxycarbonyl-glycyl-L-proline (ZGP) and a diol-bonded HPTLC phase. These plates are firstly pre-washed with dichloromethane and then dipped in the mobile phase to impregnate them with the reagent. The mobile phase consists of a 5 mmol L^{-1} solution of ZGP and 0.4 mmol L^{-1} ethanolamine in dichloromethane. In one method the samples were applied to the plate followed by continuous developments to *c.* 4 cm for 10–20 min. The plates were then dried and the process repeated. Solvent composition for this type of IP-TLC can be critical, and in our hands the inclusion of 2% v/v ethanol to the dichloromethane is essential in order to obtain separation of the enantiomers. With less than this amount of ethanol, no resolution is obtained whilst higher proportions result in increased R_F values for the analytes and a loss of resolution. Sample loading is also an important factor: the best results are obtained with loadings of propranolol of *ca.* $5 \mu\text{g}$ applied as a 1 cm band.

Conclusions

IP-TLC can be used to advantage for the modulation of the chromatography of acidic and basic analytes on a range of stationary phases. The way in which the reagents are used (i.e. in the mobile phase or impregnated on to the plate) depends on the structure of the reagent itself and the nature of the stationary phase. Probably the most important factors controlling the magnitude of the effect obtained when using an IP reagent in planar chromatography are the structure of the reagent (with long chain reagents giving the biggest effects) and the concentration of reagent employed. In contrast to HPLC, pH has relatively little effect in many IP-TLC systems.

Copyright © 2000 Academic Press

Although many new tools, such as high performance liquid chromatography (HPLC) and capillary zone electrophoresis, have been developed for the analytical laboratory, none can be used as quickly or inexpensively as planar or thin-layer chromatography (TLC). This tool can be used as a complete analytical system (from initial separation to final quantitation) or as a stepping stone or aid for other analytical methods. It is one of the few analytical tools that requires no sample clean-up, saving time and money. Many samples can be applied and analysed at the same time on a single TLC plate. With the combinatorial chemistries now being used to develop new drugs, renewed interest in this high throughput tool has become apparent.

One distinct advantage, often overlooked, is that when using TLC for any screening or method development, it shows components at the origin that do not move and will over time contaminate other analytical systems, such as an HPLC column. This potential problem would not be apparent if optimizing solely on the HPLC system. Likewise, samples applied after sample preparation would show whether or not sufficient clean-up was actually accomplished with the sample preparation technique used. This can save countless hours of frustration that would develop long after the initial method was thought to be sufficient for the analytical results needed.

Planar chromatography is also useful when optimizing a solid-phase extraction (SPE) method, when

many SPE tubes and extracting solvents will be tried. Up to 20 samples can be spotted on each side of a 20 × 20 cm TLC plate (Figure 1). Each side can be developed in 10–20 min to just 6–8 cm. A quick look under UV light or spray visualization can show the presence or absence of a compound of interest. This is certainly many times faster than doing the 40 samples on an HPLC system, one at time.

Samples from any fast TLC screening which are found to be positive for the component of interest can be confirmed or further quantified with TLC by applying standards and using densitometry or can be transferred to another analytical technique.

This is a brief review of the layers most often used and referenced in planar chromatography. For details on less used layers or more information on those discussed, the reader is referred to the Stahl book listed in the Further Reading section. A few recommended methods or tips are included within each section, where their use will improve performance or the property of a plate or separation.

Figure 1 Multi-spotted 20 × 20 cm TLC plate.

Silica Gel

Classical TLC began with silica gel layers and these continue to be the most used today. Silica gel can be used with any solvent system for a separation – from nonpolar to polar, thus accounting for its versatility. **Table 1** shows a list of compounds and classes which can be separated on a silica gel layer.

The separation mode on a silica (or other oxide layer), when a mostly nonpolar mobile phase is used, is the adsorption mode. This mode separates the compounds according to general polarity classes, which is often a necessary initial step if dealing with a multi-component/multipolarity mixture.

The solvents for this mode also contain some polar modifier to balance the selectivity of the silanol sites,

Table 1 Compounds and classes separated by silica gel TLC

Amino acids, derivatized	Flavonoids
Abused drugs	Flavours
Aflatoxins	Fungicides
Alkaloids	Ginsenosides
Allergans	Glycerols
Amines	Glycols
Anaesthetics	Herbal medicines
Analgesics	Herbicides

50	60

so selective elution is possible. The details for some of these solvent systems are found in other parts of this article in classical texts and in current literature.

The silica gel used for TLC was derived from the silica gel used for column chromatography, placed into a mortar and pestle and reground to a finer particle size. Since the standard pore size for silica gel for column use was 6 nm, this became the *de facto* standard for TLC. Other pore size silica gels are available (4, 8 and 10 nm), but these are not as widely used and so definite conclusions about their possible selectivity differences compared to the 6 nm material cannot be drawn. One difference that could be important is the difference in the surface area of these silicas, as can be seen in **Table 2**. As the pore size increases, the surface area decreases. With less surface area and wider pores, larger molecules, such as biopolymers, separate better.

Also very important in the use of silica gel is the type of silica generated in the manufacturing process. There can be different types of silanols present, as shown in **Figure 2**. The best synthetic method should produce the most homogeneous surface, so that there are no (or minimal) numbers of surface areas of increased binding (with geminal or vicinal silanols), but mostly free silanol sites. Such a silica gel would produce the most symmetrical bands on the plate, with little tailing evident.

There are two particle sizes of silica gels used to make TLC plates. The classical size range is 15–40 μm , which is currently used for most 20 \times 20 cm plates. The newer size range is 3–8 μm and this is used for high performance TLC (HPTLC) plates. As with any chromatographic technique, a smaller particle can give higher efficiency to a separation, is faster since shorter development distances

Figure 2 Possible silanol types on silica gel.

are used, and gives more compact spots so the limits of detection are improved. The performance of the HPTLC plates can be further improved if the semi-automatic or automatic devices (Camag, Desaga) are used for spotting and development. For the most part, however, the standard manual spotting techniques and the large volume developing chamber are used for both TLC and HPTLC for routine screening work.

The selectivity and activity of silica gel are determined to a large degree by the amount of water held on to its surface. Generally, a plate is activated to drive off excess water by placing it in an oven at 100°C for 20–30 min. After cooling to room temperature, however, it begins to re-adsorb the atmospheric humidity and rapidly hydrates again. This is not bad, since a completely dry silica would retain compounds too strongly and would need much stronger solvents to move the components.

Chemically Bonded Layers

An ever-expanding line of special phases, many developed first for use in HPLC, are now available as a thin layer. Although their use is not widespread, there are many reasons for using them since they can be excellent scouting tools for HPLC or the reverse – taking a HPLC method and using the solvent systems on the equivalent bonded layer can give a rapid screening tool. Thus, little method development is required, with the exception of some re-ratioing of the mobile-phase components on the thin-layer plate.

The most commonly used HPLC phases are made of silica bonded with various-length alkyl chains, C₁₈, C₈, C₄, CN (cyanopropyl) or aromatic rings, e.g. phenyl. All of these bonded phases are available on a TLC plate for reversed-phase chromatography. They are used as any TLC plate, but often need some organic component in the spotting solvent, since an entirely aqueous solution will not penetrate the bonded hydrophobic surface of some of these layers. The usual methanol–water, acetonitrile–water, tetrahydrofuran–water mobile phases or other combinations of organic solvent–water with acids, bases or buffers can be used. Some highly bonded layers from certain manufacturers need a higher percentage of organic solvent to work well, and to ensure that the layers will not lift away from the support. If a higher percentage of water needs to be used with such layers, the water portion can be made up of 0.5–1 mol L⁻¹ NaCl to help the layer remain intact through the development. Some manufacturers have produced reversed-phase layers that are compatible with solvents containing up to 100% water in the mobile phase.

Other polar bonded layers, like NH₂ (aminopropyl), CN and Diol (propanediol) are often used as a substitute for silica gel with the same type of – mostly nonpolar – mobile phases, but they can also be used with polar mobile phases to accomplish different separations and selectivities.

Aluminium Oxide (Alumina)

Although many metal oxides have been used for TLC, only aluminium oxide has found much use and is available from manufacturers as prepared plates. It can have a vastly different selectivity compared to silica gel since its surface is composed of positive and negative charge sites, with no equivalent to a silanol. Its activity is also very much tied, to the water content on its surface and it is also used with activation. Another difference in this sorbent compared to silica gel is the possibility of making it with a wide range of different pore sizes (6, 9 and 15 nm). Alumina can also be made with acidic, neutral or basic surface character, which provides a range of possibilities for use depending on the compounds being separated. Thus, with a basic layer, acidic components would not move at all, so selective separation (in this case, capture) can begin at the origin where the spotting is done. Thus, a completely different arsenal of analytical tools can be found with these layers and in method development the different layers can be tried side by side to determine the effect of the different surface pHs.

The various-pH alumina layers have been used for separations of alkaloids, amines, antibiotics, lipid, nucleosides, pigments, polyaromatic hydrocarbons, steroids and surfactants. Many researchers seem to fear possible decomposition of components on alumina layers, but this is probably an unfounded myth, and would be just as possible on any high surface area exposed to an oxygen-containing atmosphere and a laboratory with fluorescent lighting.

Cellulose

Another classical column packing made smaller and applied to planar chromatography is cellulose. It has less polarity than an oxide and is hence a much milder sorbent for separation. It is mostly used as a partition chromatographic medium, for separating amino acids, analgesics, antiarrhythmics, antibiotics, carbohydrates, flavonoids, herbicides, inorganic ions, polyaromatic hydrocarbons, phenols, phenolics, pigments and proteins. Its largest use today is for determining amino acid composition using a two-dimensional method (spot in one corner, develop in one direction with one solvent, dry, turn 90° and develop in the

second direction with another solvent). Two-dimensional development gives a much better separation of the > 20 amino acids which can be determined with this method. Some chiral separations have also been performed on cellulose layers, since it possesses a crystallinity that attracts one enantiomeric form more than the other. This chiral recognition can be enhanced and improved by using derivatized celluloses as layers, e.g., acetylcellulose and benzylcellulose.

Polyamide

Polyamide is a sorbent made from the polymer nylon. As the name implies, it has amide linkages throughout the structure, allowing excellent hydrogen bonding to occur on the surface. It has found use in the separation of alkaloids, amino acid derivatives, anilines, antioxidants, catecholamines, dyes, indoles, lactones, nucleotides, -sides, -bases, pesticides, phenols, steroids, sugars, sulfonamides, thiamines or any organic structures with OH or COOH or CHO groups. The mobile phases used on such a layer are as varied as they are for silica gel. For instance, hexane–diethyl ether–acetic acid (1 : 1 : 0.1) has been used for barbiturate separations, benzene–ethyl acetate–formic acid (5 : 10 : 2) has been used for artificial sweetener separations, and water–95% ethanol (6 : 4) has been used for sulfonamide separations. There are a few references to its use (see Further Reading).

Kieselguhr (Diatomaceous Earth)

Kieselguhr or diatomaceous earth is an amorphous silica of fossil origin. Once mined and carefully cleaned, it can be used as a support for TLC. It has a very wide pore size, and very low surface activity compared to silica gel and other TLC sorbents. Because of its inactivity, it is often impregnated with paraffin oil, silicone oil, or similar and used for reversed-phase partition chromatography. Some manufacturers have a prepared TLC layer of a 1 : 1 mixture of silica gel and kieselguhr. It performs like a less active silica gel, with faster mobility of the solutes compared to a pure silica gel layer.

Ion Exchangers

A few ion exchangers derived from cellulose or resinous backbones are available for traditional ion exchange separations. Obviously, these layers are used for separations of ionic compounds, from pharmaceuticals to inorganic salts. These can be found with both weak and strong exchange sites. Ion exchange cellulose layers include diethylaminoethyl (DEAE,

a strongly basic anion exchanger), ECTEOLA (treating alkali cellulose with epichlorohydrin and triethanolamine, a weakly basic anion exchanger), PEI (impregnating cellulose with polyethyleneimine, a strongly basic anion exchanger). The PEI cellulose is widely used to separate nucleic acid derivatives. The resinous layers include the SA (strongly acidic cation exchanger) or the SB (strongly basic anion exchanger). Researchers with an interest in reading more about these and their possible separations should consult the texts in Further Reading.

Impregnated Layers

TLC layers with special properties can be made by adding reagents to the silica gel slurry when the plates are made, or after, by dipping the prepared TLC plate into reagent solutions, or predeveloping them with the reagent solution. Since the prepared layers of this type are limited, and might age if not used, they are prepared mostly by the latter two methods. After drying and activation, they are used in the normal manner.

The most often used impregnated layer is that made with a 1–5% solution of silver nitrate in methanol. This impregnation allows geometric *cis/trans* or C=C bonded isomers to be separated, usually with various lipid mixtures. If made by impregnation, they must be dried and stored in the dark, and wrapped in aluminium foil so that oxidation caused by light does not occur.

Other useful impregnated layers found in the literature include 1% potassium oxalate aiding in the discrimination of polyphosphoinositides, 5–10% magnesium acetate aiding in the separation of phospholipids, and 5% ammonium sulfate, which allows a TLC plate to be charred without spraying with sulfuric acid or other reagents. Whether this dry reagent charring does as good a job for a particular class of compounds as other charring reagents should be investigated.

Pre-scored, Channelled, Preconcentration Zone and Preparative Plates

Other physical devices are also available on thin layers to increase the versatility of the technique. One is the pre-scoring of the glass plate on the back to allow a 20 × 20 plate to be broken into 5 × 20 or 10 × 20 plates. Likewise, a pre-scored 10 × 10 cm HPTLC plate can be broken into 5 × 10 and 5 × 5 sizes (Figure 3). This allows the user to break the plate according to the number of samples needing to be run, to save on plates.

Figure 3 Pre-scored TLC plates.

Other plates have channels placed on the layer about 1 cm apart, 1–2 mm wide, to separate one lane of silica gel from another (Figure 4). Originally it was used to give a blank lane for densitometry background correction, but became widely used to keep samples separated when drugs of abuse testing was done in the 1960s. Now most initial drugs of abuse testing is done with EMIT (enzyme multiplied immunoassay technique) and radioimmunoassay techniques, with confirmation by gas chromatography–mass spectrometry.

Preconcentration Zone

One of the most useful tools designed into a thin layer plate is the preconcentration or pre-spotting zone (Figure 5). This is a 2.5–4 cm area at the bottom of a plate, composed of diatomaceous earth or wide-pore silica gel, to allow heavy loading or vertical (horizontal if doing preparative work) streaking of the sample. As the mobile phase passes through this special material, the sample does two things. If a circular spot, it changes to a band (an oblong circle). If a dilute sample, it also concentrates itself in this band. In this portion of the plate, no separation occurs. The separation begins only after the band transfers from the preconcentration zone into the silica (or, in some cases, the RP18 or other bonded-phase) layer. This

Figure 5 Progressive separation on a preconcentration zone plate.

reforming of the sample (from a spot to a band) gives a more efficient separation, since the band is narrower along the direction of development.

Preparative Layers

These are thicker layers of any of the above sorbents to allow larger quantities of sample solutions to be applied. These layers are 0.5, 1 or 2 mm thick (compared to the usual analytical thickness of 0.25 mm). Usually the sample is applied to the plates as a streak by some automatic device. The thicker the layer, the more sample solution that can be applied (Figure 6). Such a plate is used in the traditional manner, but will generate greater heat of solvation if using a silica plate with a developing solvent with a polar modifier. This will make spots or bands travel faster, and a readjustment of the solvent ratios may be necessary to reduce the band travel.

Binders

Many sorbents made into thin layers do not form a layer that adheres sufficiently strongly. Good binding ability is required so the plate can be handled during activation, spotting, developing and visualiz-

Figure 4 Channelled TLC plate.

Figure 6 Streaked and developed preparative TLC plate.

ation. If any layer is lost or weakened, then the separation accomplished is lost. A binder of some kind is added to the sorbent formulation when making up the thin-layer plates.

Classically, the binder used for silica gel layers was calcium sulfate hemihydrate (plaster of Paris) added between 10 and 15% by weight. After slurring with water and being applied to the plate, it begins to form the dihydrate within a few minutes. This is called setting and the layer becomes semi-rigid as the water is chemically removed. After further drying, the binder effectively holds the slurry to the glass support. This binder forms what is considered a soft layer, with only a slight resistance to abrasion. As a result, a silica gel G layer needs care in use so that the fragile layer is not damaged when spotting or being moved to and from the developing chamber. This plate is made commercially by only one manufacturer in the USA, or by special order. Most often it is a binder formulation used by researchers making their own plates. Its main advantage is that any spots on such a layer are easily removed for subsequent work.

An alternative binder is a hydrated or fused silica gel, often designated H. A few per cent of this binder also gives a suitable soft-layer plate. This binder is most often used when interference by the calcium sulfate of a G-type of plate has to be eliminated.

Because of the fragile nature of the G and H binders, most planar chromatographic plate manufacturers use polymeric binders. Such polymer binders give a moderate to hard layer that withstands all handling done throughout the TLC process so the integrity of the layer is not harmed. Any damage to the surface done during activation, spotting or visualization can create artefacts and/or affect the results of the chromatography. These plates easily accommodate all stacking, shipping and user steps, and have the selectivity of the classical G-type plate.

The binders used are proprietary but are generally based on a water-soluble polymer such as polyvinyl alcohol (PVA) or polyvinyl pyrrolidone (PVP). These are added to the slurry in a few per cent by weight. They cross-link during drying and heating. They can be made stronger, generally, by reheating before use. This reheating or activation helps not only to dry the silica gel plates, but also to give better reproducibility. Just as important, too, is that the heating makes the binder work better under the conditions of development, even for a reversed-phase plate which is most often going into an organic/water-developing solvent.

Such harder layers are more convenient to use, allowing marking or writing on the top of the plate for identification purposes. Some are more difficult to

spot since the binder imparts some water resistance to the layer. By adding from 5 to 10% ethanol to any aqueous sample (or spray reagent for visualization) the viscosity of the aqueous solutions is dramatically decreased so that penetration into the layer is not a problem.

Often different binders are used on bonded silica gel layers since getting the nonpolar C_{18} silica to stick to a polar glass surface is more difficult. Frequently, too, the bonded phase on a TLC plate is lighter (a smaller percentage by weight) than on the HPLC version to allow a greater solvent range (high or low water content) to be used.

These polymeric binders allowed alternative supports such as aluminium and plastic (usually a polyterphthlate) to be used as supports in addition to glass. With the correct percentage of binder, a certain amount of flexing can be done without cracking or lifting of the layer from these supports. The advantage of these backing materials is that they can easily be cut for resizing or removal of the separated spot. Such plates also allow easy storage, whether stored in the original box or punched and inserted in a file.

If trouble with a binder, such as lifting or bubbling, is observed, the binder may only need re-curing, i.e. reheating, to ensure greater cross-linking and strength. As mentioned above, it is recommended that all TLC plates – silica gel and bonded layers – be heated not only to remove absorbed water but also to make the binder stronger for subsequent steps.

If extraction is to be done from a plate to recover the analyte, the plate should be predeveloped overnight in the solvent (or solvent combination) to be used for the extraction. This will remove unpolymerized binder so it will not wash out into the extract and possibly interfere with further work or characterization. To remove any portion of silica gel from a polymer-bound plate, first wet the area by spraying with methanol-water (1 : 1) to soften the binder. It can then be removed with little flaking or dusting.

Other types of layers that have been around for a number of years are the impregnated and incorporated layers. With the impregnated layer, a fibrous support such as cellulose filter paper or fibreglass paper is impregnated with a silicate solution, treated and dried to form a type of silica gel or hydrated silica. It is very fast, but low resolution separation medium.

With the incorporated layers, the silica gel or bonded silica gel is mixed with fibres of a polyfluoro (or other solvent resistant formulation) polymer and a mat of the combination is cast (like a cellulose paper would be made) and processed to form a sheet. No binders need be added to either of these two types of

layers, but a percentage of the matrix plays no part in the separation.

Often cellulose, alumina and polyamide layers need no additional binders, since their physical properties allow them to form a strong surface bond with the different supports. This can be a combination of hydrogen-bonding ability and fibrous nature of the cellulose, the hydrogen-bonding ability of polyamide, and the particle size range of the alumina.

Supports

Most of the classical layers were prepared on glass since it was generally available and easily handled. It could be cut to any size and Camag and Desaga made special devices for holding the glass plates and dispensing the slurries. The glass had to have an especially smooth surface and often the edges were smoothed to prevent cuts to the operator's fingers while the plates were handled. Any glass used to prepare the TLC plates must be carefully cleaned to remove any grease or oils that might prevent an even layer from being applied.

Pre-scored plates are discussed above, but any glass-supported plate can be cut by placing it face down on a sheet or two of paper towelling and scoring the glass with a carbide scribe (using a steady, hard motion). The plate is then lifted, held along the two edges with a paper towel, and broken, using a combination of bending (away from the score) and a pulling apart to break the plate. A final step is to remove any loose silica (or other sorbent) from the newly cut edges with a paper towel. This prevents edge effects – faster movement of the solvent at any rough, sorbent edges.

With special automated equipment, some manufacturers began to use both aluminium and polyterphthalate plastic supports. Generally, thinner layers were found to be optimal on these flexible layers, but the separations are no different from that found on a glass plate since the other items such as the binder and silica gel are the same. Although most TLC plates sold today are still on glass, some researchers feel that the ability to cut to size or the removal of components after the separation is a distinct advantage. After cutting these plates with scissors or a sharp-bladed instrument, 'edging', discussed above, should be done.

The flexible layers can sag and should be stood in a chamber at a sharper angle (Figure 7) than a rigid glass plate. This is especially true if a chlorinated developing solvent is used. If one of the impregnated or incorporated layers discussed above is used, they require a special holding device or clamps to hang them in the developing chambers, as was used for paper chromatographic separations.

Figure 7 Positioning of flexible-backed TLC plates in a developing chamber.

Fluorescent Indicators

Detection is a special problem which must be considered when beginning a separation. Since most compounds are colourless, this might require considerable time to find the best reagents to spray on to a plate to visualize the components found in the sample. Such spray visualization might need a series of reagents to reveal the different species found in a complex mixture, such as with drugs of abuse.

One method used since the early days of TLC has been incorporation of a fluorescent indicator in the layer. A few per cent by weight of an inorganic salt such as manganese-activated zinc silicate, zinc cadmium sulfide, and others can be used. When visualizing a compound that can absorb the particular wavelength of light used to activate the fluorescent indicator, it will appear as a dark spot against the background fluorescence of the plate. This fluorescent indicator is often activated with either 254 or 366 nm wavelength light. It then fluoresces green, light blue or off-white. Other colours may be seen, too, but these are usually found when an organic fluorescent indicator is used. These latter indicators are often sprayed on after the plate is developed and dried, since they can move with many mobile phases that might be used for developing the plate.

The wavelength of the activation is usually stated after the F designation used by many manufacturers. One other item that might be important regarding fluorescent indicators is the fact that some might not be stable if exposed to strong acids like hydrochloric or sulfuric (i.e. mineral acids). Such strong acids can change the crystal structure of the inorganic salts and make them nonfluorescent. Usually this does not present problems since the fluorescent detection is tried as soon as the plate is dried, and before any other reagents are sprayed on to it for further detection of other types of compounds – ones that would not fluoresce or quench.

Conclusions

Although a simple analytical tool, TLC continues to be an important screening and scouting method for almost all industries. The various TLC layers and supports discussed above are available worldwide and the large amount of literature available continues to show the versatility of this tool. These products allow the chromatographer a wide range of possibilities for attacking an analytical problem with some knowledge and the confidence that success will be attained with a few plates and a few solvent systems.

Introduction

Thin-layer chromatography (TLC) and high performance thin-layer chromatography (HPTLC), collectively often referred to as planar chromatography, in combination with *in situ* mass spectrometry (MS), provides a reliable means for the unequivocal identification of substances separated by this type of chromatography. More specifically, the ability to obtain mass spectrometric information from the separated analytes directly from the TLC/HPTLC sorbent obviates the need to recover the analytes of interest prior to analysis. Although TLC-MS is a useful method of separation and detection, it does have its limitations where complex matrices are encountered. However, tandem mass spectrometric (MS-MS) techniques can be used to enhance the mass spectral data by reducing the interference caused by coeluting analytes or general background noise generated by excipients on the plate.

Practical Considerations

Where the resolution of the separation is high, such as in capillary column chromatography, identification of components based on retention time is a well-established practice. Planar chromatography as normally practised does not achieve a separation efficiency equivalent to that obtained by column chromatography.

Consequently, the identification of components separated by planar methods based solely on R_F values and UV or fluorescence properties will always leave a higher degree of uncertainty about the true identity of the compounds present. Positive identification of unknowns has to be made by subjecting the analyte to a spectroscopic technique such as mass spectrometry.

As with other methods of chromatography, the use of MS as a TLC/HPTLC detector involves the detection and identification of the analyte in the presence of interfering materials from the chromatographic mobile and stationary phases. An analyte separated by planar techniques will be presented to a mass spectrometer along with the stationary phase, any organic phase modifier present, binding agents and fluorescent indicators. It is possible that residual solvents from the mobile phase, some of which may have high boiling points may be present. At best, the mass spectra obtained from a single spot taken from, for example, a silica gel HPTLC plate, will contain ions from the analyte with contributions from all these other compounds. When ionization is by fast atom bombardment (FAB) the situation is exacerbated by the formation of matrix and salt ions. Although useful information can be obtained from TLC/HPTLC-MS experiments, the information so obtained can be improved by using tandem mass spectrometric methods.

Mass Spectrometric Benefits of Planar Separations

The advantages of HPTLC to the mass spectrometrists are equally important. The contribution made by the

chosen detector in evaluating a separation method is often ignored. It is often assumed that the detector of choice is equally sensitive to all analytes presented to it and that the separation method and the detector do not influence each other. As a result, universal detectors that couple high sensitivity, specificity and selectivity are in great demand. A mass spectrometer is such a device. However, the operating limits of the mass spectrometer place some restraints on the chromatographic method of choice. Although the ionization of analytes may be considered as instantaneous, mass analysis is not. However, planar separations do not impose the same constraints on the mass spectrometer since the chromatography is completed prior to the analytes being presented to the mass spectrometer.

Planar Separations as a Sample Clean-up Process

A further use of HPTLC is where the chromatography is simply a clean-up process, or a purification step. The planar separation can be used to remove impurities such as plasticizers or high boiling hydrocarbons. A solvent system can be used that will allow the migration of the contaminants up the plate but will leave the sample of interest at, or close to, the origin. The purified analyte can then be introduced into the mass spectrometer by one of the methods described below.

Instrumentation

The approach to analysis by TLC/HPTLC-MS may be divided into two basic methods: instrumental and manual. The instrumental method involves the use of an automated probe onto which the whole chromatogram is attached. With this method, the integrity of the chromatogram is retained, but is restricted to ionization in the liquid phase by methods such as FAB and the related technique of liquid secondary ion mass spectrometry (LSIMS).

The manual technique involves the removal of the zone of interest from the plate. After removal, the analyte may be extracted from the sorbent prior to analysis, or analysed directly from the sorbent. The manual method is readily implemented and requires no further equipment or interfaces. Also, the classical vapour-phase electron and chemical methods of ionization (EI/CI) can be used.

Sample Application

The most common method of application, and that most suited to MS applications when MS analysis is to be straight from the adsorbent, is by a glass capillary as a spot ('spotting'). For single MS

experiments a single spot is usually sufficient. Where multi-MS experiments are to be performed, such as when tandem mass spectrometry is to be used, the application of a row of replicate spots is the preferred method, the separated analytes from a fresh spot being used as those from a previous one become exhausted. If the analytes are to be removed from the adsorbent before analysis by MS the application of a short line ('streaking') has been found to be the best method. Whether the *spotting* or *streaking* method is used, care is needed during application to keep the analyte origin as compact as possible. A sample that is too large causes poor-quality separations due to the analyte diffusing and causing the spot to broaden. Quantities of sample spotted are in the range of 1–50 $\mu\text{g } \mu\text{L}^{-1}$, 1–10 μL being applied to the plate by multiloading a 1–5 μL capillary.

Care has to be taken not to damage the surface of the adsorbent as this causes the mobile phase to elute unevenly, resulting in distorted spots and so leading to a loss of chromatographic resolution. The type of matrices being studied and the detection limit of the mass spectrometer are then the critical factors in determining to what extent analysis is possible. However, when sample loading needs to be high, the deconvolution-by-mass capabilities of the mass spectrometer often compensate for the reduction in resolution.

Sample Introduction after Planar Separation

Although analysis by planar chromatographic techniques and mass spectrometry has been practised for many years, there remain three principal methods of sample introduction.

The first method involves the analyte of interest being recovered from the adsorbent by elution with an appropriate solvent and introduced into the mass spectrometer's ion source as a discrete sample. After the area of interest of the chromatogram has been identified, usually by visual means, the perimeter of the area of interest, the 'spot', is marked with a soft-leaded pencil. The adsorbent is loosened from the backing with a flat-bladed tool such as a spindle screwdriver or microspatula. The loosened material is removed from the plate and mixed with a small quantity of solvent. Ultrasonication can assist in the extraction process. A small plug of quartz wool packed into a drawn-out Pasteur pipette (Figure 1) acts as a filter medium. The filtered adsorbent is washed with one aliquot of solvent.

Depending upon the method of ionization to be used, the extracted material may be introduced into the ion source by using the direct insertion probe for the ionization of volatile analytes by EI/CI; or by a desorption probe or cassette, such as for analysis by

Figure 1 Analyte recovery by solvent elution.

FAB, LSIMS or MALDI (matrix-assisted laser desorption ionization), for the ionization of polar, non-volatile and/or thermally labile analytes. This method of sample introduction is particularly useful when the sample application methods of multispotting or streaking methods are used to obtain sufficient analyte for multi-MS-MS experiments.

In the second method the analyte and adsorbent are not separated. Both are introduced into the ion source simultaneously. After visual location, the spot is scraped off the plate and introduced into the ion source by one of the methods described above.

Both of the above methods destroy the integrity of the chromatogram. A third method of introduction uses a dedicated probe that enables the whole chromatogram to be introduced into the FAB/LSIMS ion source, so that a spatially resolved total ion current chromatogram of the organic material on the adsorbent may be obtained. With this type of probe it is necessary to use aluminium-backed plates. A strip approximately 10 mm × 65 mm, which is essentially one track of a developed plate, is cut out and mounted on the end of the probe. An appropriate matrix is painted down the length of the strip and the chromatogram is driven at a constant rate, with a maximum of 50 mm min⁻¹, by a stepping motor. The pulses to the stepping motor are controlled in conjunction with the scan control of the mass spectrometer, with the result that the whole chromatogram is scanned by the FAB/LSIMS beam. Mass spectral information is acquired for the whole chrom-

atogram. The analysis is analogous to the column chromatography experiment in that the analytes are ionized sequentially throughout the chromatogram.

Sample Concentration

As the HPTLC plate develops, spot diffusion occurs with the result that what was 0.5–1 mm spot at the origin may well be 5 or 6 mm in diameter after complete development. Thus the analyte may well be distributed over 10 times more adsorbent than when at the origin, with the result that when the analytes are introduced into the ion source along with the adsorbent and other extraneous compounds from the plate there is considerably more adsorbent than analyte presented for ionization. Because there is a finite amount of material that can be introduced into the ion source, occasions may arise where there is insufficient analyte available from which good quality mass spectral data may be obtained. Several methods of sample concentration have been devised to overcome this natural spot diffusion phenomenon. For example, an analyte spot can be encircled with a ring of solvent. As the solvent diffuses through the adsorbent the analyte will slowly migrate to, and concentrate at, the centre of the spot. The concentrated spot can then be removed and analysed.

An alternative is where, after chromatographic development on aluminium- and plastic-backed plates, the edge of the plate may be trimmed off using dress-maker's pinking shears. This leaves the plate with a regular saw-toothed edge. The plate is rotated by 180° followed by the application of solvent. The analytes are thus concentrated into the tips of the triangular-shaped segments of the plate. Once concentrated, the zone may be removed from the plate and introduced into the ion source as previously described.

A general method not confined to aluminium- and plastic-backed plates involves scribing a trapezoidal line around the sample spot (Figure 2). A strip, 1–2 mm wide, of the adsorbent on the outside of the

Figure 2 Zone concentration.

Figure 3 Zones (A) before and (B) after concentration.

line is removed. Then, from a 100 μL syringe, a quantity of an eluting solvent is slowly deposited on the base of the spot. After several tens of seconds the analyte condenses at the top of the trapezoid (Figure 3). The concentrated analyte and adsorbent are removed from the plate and are introduced into the ion source as described previously.

This method of spot concentration completely overcomes the need to overload the plate, with associated loss of chromatographic resolution, to enable sufficient sample to be introduced into the mass spectrometer for ionization. It is highly satisfactory prior to both vapour-phase and liquid-phase ionization.

Obtaining Mass Spectral Data

Vapour-Phase Ionization of the Analytes Directly from the Adsorbent

Where the analytes are volatile and thermally stable and are to be ionized by EI/CI, the zone of interest is concentrated as described earlier and a portion of the adsorbent is placed in a standard quartz sample tube. A small plug of quartz wool is placed on top of the sample to prevent the fine silica being sucked out of the tube during evacuation. The sample tube is then fitted to the direct insertion probe. The volatile analyte is desorbed by heat from the involatile adsorbent.

Where ionization is by MALDI, various methods have been described that enable mass spectra to be obtained directly from the TLC plate. TLC-MALDI takes advantage of the ability of MALDI to ionize fragile, low and high molecular weight compounds with a high degree of sensitivity and without significant fragmentation.

Liquid-Phase Ionization of the Analytes Directly from the Adsorbent

For polar, nonvolatile analytes, the spot is concentrated as described above. The adsorbent is then removed from the plate and slurried directly on the desorption probe with the chosen matrix.

Reducing Surface Effects during FAB/LSIMS Ionization

When compounds with high surface activity properties are present in a mixture, even as minor components, they have been shown to suppress the ionization of the major components during analysis by FAB/LSIMS-MS. Compounds such as surfactants possess these properties to such an extent that analysis by liquid phase ionization is unpredictable. Often the major component (of interest) is suppressed so much that it may not appear to be the major component at all. Planar chromatography has been shown to be an effective way of separating such suppressants from the analyte of interest.

Solo Mass Spectrometer versus Tandem Mass Spectrometry

As described previously, the use of MS as a TLC/HPTLC detector involves the detection and identification of the analyte in the presence of interfering compounds from the chromatographic process. At best, the mass spectra obtained from a single spot after planar separation will contain ions from the analyte and from these other compounds. When ionization is by FAB/LSIMS the situation may be exacerbated by the formation of matrix and salt ions (Figure 4). Although useful information can be obtained from TLC/HPTLC-MS

Figure 4 FAB-MS spectrum of paracetamol obtained from urine following ascending chromatography on diol bonded phase.

experiments, the information so obtained can be improved by using tandem mass spectrometric methods.

Tandem mass spectrometry is now a well-established analytical technique. Tandem mass spectrometry offers advantages in three major areas: structure elucidation of organic and biological molecules; the identification of components in complex matrices with or without chromatographic separation; and in trace analysis.

Several types of instrument capable of performing MS-MS analyses are available, the two most common types being the triple-quadrupole and the sector/quadrupole hybrid. In both types of instrument the ions selected in the first analyser are transmitted into the reaction region, normally a gas cell, where frag-

mentation occurs by collisions with a target gas, to yield characteristic product ions to be analysed and detected by the second analyser (Figure 5).

Ionization in Tandem Mass Spectrometry

Although all of the currently available methods of ionization are applicable to tandem mass spectrometry, where planar separations are involved the choice is limited to EI/CI and FAB/LSIMS. Although electron ionization (EI) is still the most commonly encountered method of ionization, and is used extensively in MS-MS studies, ionization methods such as FAB/LSIMS and CI, which normally produce intense ions providing molecular weight information, are preferable. It is desirable to produce as few ions of different m/z values as possible when using MS-MS following planar separations.

The benefits of FAB/LSIMS and CI are two-fold. First, they usually produce a spectrum with fewer interferences, enabling easier selection of precursor ion. Second, an increase in sensitivity is often achieved if all the ions current obtained from an analyte is concentrated in one ion.

Ion Dissociation in Tandem Mass Spectrometry

Although the MS-MS instrumentation is extensive, there is only one basic principle: the measurement of the mass-to-charge ratios of ions before and after dissociation in the reaction region. The change in mass of an ion carrying a single charge is the most commonly measured process and can be represented by the following equation:

where M_p^+ represents the precursor ion, M_d^+ represents the product ion and M_n represents the neutral fragment. The precursor ion may be the ion representing the relative mass of the species but need not necessarily be so; the precursor ion could be any ion formed within the mass spectrometer. However, molecular ions, and ions generated within the ion source, are the major subjects of MS-MS experiments. The product ion, M_d^+ , represented in the above equation may be one of many fragment ions formed by simultaneous dissociation within the reaction region, and as such indicates a direct relationship between it and the precursor ion. The neutral fragment M_n , being uncharged, is not normally detected. However, since M_p^+ and M_d^+ are measured the mass of the neutral fragment may be calculated by difference. These three variables form the basis of most MS-MS experiments and it is this basis that makes tandem mass spectrometry such a powerful analytical tool.

Figure 5 (A) FAB-MS-MS collision induced dissociation product ion spectrum of the $(M+H)^+$ ion from a standard sample of paracetamol following ascending chromatography on diol bonded phase. Collision energy, 60–40 eV; collision gas, argon at an indicated pressure of 3.0×10^{-6} mbar. (B) FAB-MS-MS collision induced dissociation spectrum of the $(M+H)^+$ ion from paracetamol extracted from urine and following ascending chromatography on diol bonded phase. Collision energy, 60–40 eV; collision gas, argon at an indicated pressure of 3.0×10^{-6} mbar.

Scan Functions in Tandem Mass Spectrometry

Although there are several scan functions that can be performed by tandem instruments, the most commonly used function in TLC/HPTLC applications is the product ion scan. The analytical characteristics of TLC/HPTLC-MS-MS product ion analysis contrast it with analysis by chromatography–chromatography–mass spectrometer.

Even so, just as with conventional MS, tandem mass spectrometry has its limitations. MS-MS cannot easily differentiate between isomeric and isobaric species. Isomers tend to produce similar product ion spectra and, since they cannot be separated by mass, two isomers transmitted into the gas cell simultaneously will give a product ion spectrum that is representative of the sum of the individual compounds.

Similarly, if isobaric components of the same elemental composition but of different structure are focused by the first analyser, transmitted into the gas cell and dissociated by collisions, the product ion spectrum obtained from the second analyser will be a compilation of product ions from the two components. It can be seen, therefore, that some form of chromatographic separation such as TLC/HPTLC prior to ionization can enhance the separative and characterization powers of the tandem mass spectrometer. Conversely, the use of MS-MS can greatly enhance the identification and characterization of isomeric and isobaric species separated by planar chromatography.

Conclusions

The use of MS and MS-MS as methods of detection in TLC and HPTLC separations is now well established and has been shown to be a powerful tool in the analyst's armoury. In practice, HPTLC-MS-MS has been shown to be no more technically demanding than traditional TLC-MS, yet the information provided is more detailed. Structurally important diagnostic ions are more easily observed by the elimination of matrix ions and general background clutter. Planar separation should be considered as a complementary technique alongside column methods of chromatographic separation where detection is by mass spectrometric methods. It can be applied to a wide range of polar and nonpolar analytes and is amenable to vapour-phase and liquid-phase methods of ionization. Moreover, where ionization is by laser desorption, separation by planar techniques may be the only choice.

Modes of Development: Conventional

T. H. Dzido, Medical Academy, Lublin, Poland

Copyright © 2000 Academic Press

In the conventional mode of development in planar chromatography the mobile phase is supplied to the chromatographic plate by direct contact with the adsorbent layer and the flow rate of the eluent is controlled by capillary forces.

The main modes of chromatogram development are linear, circular and anticircular. The most popular mode is linear development owing to its simplicity; no sophisticated equipment is used to apply the eluent to the chromatographic plate, as it is in circular and anticircular modes. In practice, linear development provides the resolution and reproducibility required for most qualitative and quantitative determinations. All three modes can be extended by applying continuous or multiple development.

Linear Development

Linear development is usually performed in a rectangular vessel with ascending migration of the eluent

through the adsorbent layer, from the bottom to the top of the chromatographic plate. The plate is usually positioned vertically in the developing chamber in a few millilitres of solvent. The separation of a standard lipid mixture by this mode of development is presented in **Figure 1A** and **B** by way of example. The separations were performed on a 10×10 cm pre-coated silica gel plate for high performance thin-layer chromatography (TLC), and on a conventional 20×20 cm plate (E. Merck) with eluent composed of methyl acetate-*n*-propanol-chloroform-methanol-0.25% aqueous potassium chloride (25 : 25 : 25 : 10 : 9). A conventional developing chamber (rectangular vessel) was lined with filter paper in order to ensure saturation of the vapour phase with the solvent. Samples were applied on the start line of the chromatographic plate in the form of streaks containing $0.5\text{--}3.0 \mu\text{g mL}^{-1}$ phosphorous lipid. The chromatographic process was performed at room temperature and was stopped when the eluent reached the upper edge of the plate (50 min for high performance TLC and 150 min for conventional plates). Natural lipids, cerebroside, sulfatides, phosphatidylethanolamine, phosphatidylinositol,

Figure 1 Chromatograms of standard lipids in the solvent methyl acetate-*n*-propanol-chloroform-methanol-0.25% aqueous KCl (25 : 25 : 25 : 10 : 9). (A) Separation on 10×10 cm HPTLC plate; (B) separation on classical pre-coated silica gel plate, 10×20 cm. NL, Neutral lipids; CER, cerebroside; SULF, sulfatides; PE, phosphatidylethanolamine; PA, phosphatidic acid; DPG, cardiolipin; PI, phosphatidylinositol; PS, phosphatidylserine; PC, phosphatidylcholine; SPH, sphingomyelin. phosphatidylserine, phosphatidylcholine and sphingomyelin are well separated. In addition, cerebrosides with nonhydroxylated fatty acid chains are separated from those with hydroxylated chains. Similar resolution is observed for sulfatides. The minor brain phospholipids, phosphatic acid and diphosphatidylglycerol show the same migration distance but are well separated from phosphatidylethanolamine and phosphatidylinositol.

Slightly better efficiency can be obtained in horizontal chambers. Solvent migration is not dependent on gravity and equilibration between vapour and liquid is more rapid and uniform (inner chamber volume is small). A cross-section of the horizontal DS (Dzido, Soczewiński) chamber (Chromdes, Lublin, Poland) is shown in Figure 2. Eluent can be supplied to the chromatographic plate simultaneously from its opposite edges so that the number of separated samples can be doubled in comparison to development in a vertical chamber. An example of this type of linear development is illustrated in Figure 3. The samples of a test dye-stuff mixture were spotted along two opposite edges of the 10 × 20 cm high performance TLC plate coated with silica gel. The plate was developed with toluene from opposite directions simulta-

neously. The development stops when both eluent fronts meet each other in the middle of the plate.

Another variation of linear development can be performed by changing the eluent composition during the development process (stepwise or continuous gradient elution). Samples containing components of a wide range of polarity cannot be readily separated in a single isocratic development, but the application of a gradient mobile phase can improve the separation. Figure 4 demonstrates the application of a simple stepwise gradient to increase the separation efficiency of aromatic amines. The separation was performed in an equilibrium sandwich horizontal chamber which allows delivery of very small volumes of eluent to the plate. The glass plates (5 × 20 cm) were covered with a 0.25 mm layer of silica gel, dried in air and activated for 1 h at 80°C and 2 h at 130°C. The solutes were spotted 4 cm behind the solvent front as 0.5% benzene solutions to avoid solvent demixing. A marker (azobenzene, $R_F = 1$) was spotted together with the samples to show the position of the solvent front. Two chromatograms were obtained isocratically; development with constant concentration of the mobile phase with (A) 5% methyl ethyl ketone in cyclohexane, (C) 50% methyl ethyl ketone in cyclohexane

Figure 3 Separation of dyestuff mixture from opposite directions on silica gel high performance TLC plate with toluene. 1, 4-chloro-4'-dimethylaminoazobenzene; 2, fast yellow; 3, 2-nitroaniline; 4, 4-nitroaniline; 5, phenol red.

in cyclohexane and chromatogram (B) with a two-step gradient was performed in the following manner. The plate was first developed with 5% methyl ethyl ketone. When the azobenzene spot has reached the middle of the plate the development was continued with 50% methyl ethyl ketone until the eluent front (with the azobenzene spot) has migrated to the end of the plate which protruded from the chamber. The plate

was dried and the spots were detected by spraying with aqueous sodium hydrogen carbonate and then with bis-diazotized benzidine. All the spots are well separated using the two-step gradient development as opposed to separation by isocratic development.

Figure 5 shows the densitogram of a mixture of glycosides obtained by stepwise gradient development with seven eluent fractions which were applied consecutively to the plate (pre-coated silica gel glass plate for HPTLC, 10 × 10 cm, E. Merck) using a horizontal DS chamber. The volumes and compositions of eluent fractions as solutions of methanol in ethyl acetate were as follows: (1) 0.22 ml 0.0%; (2) 0.11 ml 20%; (3) 0.11 ml 30%; (4) 0.11 ml 2%; (5) 0.11 ml 10%; (6) 0.11 ml 35%; (7) 0.11 ml 100%. Each fraction was introduced into the mobile phase reservoir of the chamber with a micropipette after the previous one had been completely absorbed by the adsorbent layer. The plate was developed for a distance of 8 cm and the glycosides were detected by spraying with a solution of chloramine in trichloroacetic acid, heating for 5–10 min at 100–110°C and scanned with a Shimadzu CS-930 densitometer at 360 nm. The densitogram shows relatively good resolution of the glycosides.

This kind of simple stepwise gradient elution can help solve difficult separation problems, especially for mixtures consisting of solutes with a wide range of polarity, e.g. plant extracts. However, for more complicated stepwise gradients, poorer retention reproducibility is obtained.

Continuous Linear Development

In conventional continuous development the end of the chromatographic plate is immersed in the eluent and the opposite end is extended out of the chromatographic chamber, allowing the solvent to evaporate

and ensuring that solvent migration is continuous and constant; development is performed over the entire length of the plate. Continuous development can also be performed using a very short distance (short bed/continuous development, SB/CD) in comparison to the normal plate length and the eluent strength should then be much weaker than in the conventional development, because several dead volumes of eluent migrate through the layer. Examples of chromatograms with continuous development are shown in Figure 6. Pure chloroform (eluent strength 0.40) and

its mixture with carbon tetrachloride (eluent strength 0.18) were applied as eluents to develop chromatograms on the silica gel G plates, 10 × 10 cm (Camag,

Figure 6 Separation of dye-stuff mixture applying continuous development on 10 × 10 cm silica gel plate with pure chloroform (eluent strength = 0.40) and with solvent mixtures consisting of chloroform and carbon tetrachloride (eluent strength = 0.30 and 0.20), solvent strength (ϵ) marked in the left top corner of the plate. New Berlin, WI, USA). Eluent strength of the mobile phase applied for the chromatograms shown in Figure 6 was 0.40, 0.30 and 0.20 (marked at the top left corner of each plate). The samples (Oil orange, Butter yellow, Sudan green and Sudan III) were spotted on the plate as benzene solutions. The emergence position (atmospheric boundary) of the plate from the chamber was 7.3 cm from the start line (position of the sample spotting) and 7.8 cm from the eluent level (immersion position of the plate in the solvent). An extraordinary increase in selectivity is observed with solvent of the lowest eluent strength (0.20). However, it is necessary to perform the development for a very long time (18 h) to maintain the same relative retentions as when using pure chloroform (0.57 h). A more efficient separation can be obtained by applying continuous development over a very short distance. The two components of the sample (Oil orange and Sudan green) were separated using SB/CD on a silica gel G plate (10 × 10 cm, Camag, New Berlin, WI, USA) for 35 min with pure carbon tetrachloride. The R_F values obtained were less than 0.05 (Figure 7 (top)). Evaporation of eluent from the plate was carried out at a position 2.5 cm from eluent level and 1.1 cm from the spotting position. For com-

parison, Figure 7 (bottom) demonstrates the results of a conventional development on a 20 cm long bed of the same adsorbent with chloroform as the developing solvent, showing R_F values of about 0.38 and a development time of 90 min. The resolution obtained by the SB/CD mode is better than continuous mode and the development time is also shorter. Additionally, the spot diameter is very small, which leads to better detection levels.

Multiple Development

This mode of development is seldom applied in practice, in comparison to conventional development, but its significance is increasing owing to its greatly increased separation efficiency. A characteristic feature of this mode is repetitive development of the chromatogram on the same plate. Each development is followed by evaporation of eluent from the plate to prepare it for the next chromatographic process. The resolution provided is greater than conventional or continuous development, and mixtures of wide polarity can easily be separated. The spots to be separated are compact, which leads to better detectability. There are three types of multiple development:

Figure 8 Comparison of (A) conventional and (B) multiple development (4 × 5) + (3 × 7) min for the separation of a mixture of PAH standards. The mobile phase was methanol-water (4 : 1) and the stationary phase octadecylsilanized silica gel. 1, Coronene; 2, benzo[g,h,i]perylene; 3, benzo[a]pyrene; 4, benzo[a]anthracene; 5, fluoranthene. (Reproduced with permission from Butler HT, Coddens ME, Khatib S and Poole CF (1985) Determination of polycyclic aromatic hydrocarbons in environmental samples by high performance thin-layer chromatography and fluorescence scanning densitometry. *Journal of Chromatographic Science* 23: 200.)

Figure 9 Chromatograms of PTH-amino acids after multiple development on silica gel plate. (A) First development with methylene chloride; (B) Second development with methylene chloride-isopropanol (99:1); (C) third development with methylene chloride-isopropanol (99:1); (D) fourth development with methylene chloride-isopropanol (97:3); (E) fifth development with ethyl acetate-acetonitrile-glacial acetic acid (74.3:25:0.7). (Reproduced with permission from Schuette SA and Poole CF (1982) Unidimensional, sequential separation of PTH-amino acids by high-performance thin-layer chromatography. *Journal of Chromatography* 239: 251.)

1. repetitive development with the same solvent in the same direction
2. repetitive development with the different solvents in the same direction
3. single or repetitive development in one direction with a given solvent, followed by single or repetitive development in the second direction perpendicular to it with another solvent (two-dimensional development)

The first mode is especially applied to the separation of poorly resolved spots, the second to mixtures of a wide range of polarity, and the third mode to separation of complex mixtures with components of similar polarity and/or different polarity.

The example of separation of polyaromatic hydrocarbons (PAH) by repetitive development with the same eluent is demonstrated in **Figure 8B**. The chromatogram was obtained with octadecyl silica layer and methanol–water (4 : 1) as eluent. Chromatogram developments were performed in an SB/CD chamber, position 4 (Regis Chemical Co.). The first four developments were performed for 5 min each and the next three for 7 min each. Between developments the plate was dried using a stream of purified nitrogen. The same PAH mixture was also separated applying conventional single development with the same plate and eluent. **Figure 8B** clearly shows the advantage of multiple development, in comparison to conventional development (**Figure 8A**).

Multiple development using change in eluent strength (stepwise gradient development) of each development stage is suitable for the separation of samples with a wide range of polarities. An example of this approach is shown in **Figure 9** for the separation of PTH-amino acid derivatives. Chromatography was performed on a 10 × 10 cm HPTLC plate coated with silica gel. The spots were applied 0.5 cm from the lower edge of the plate. The plate was developed in a short-bed continuous development chamber. The first development was made with methylene chloride for 5 min with a 3.5 cm development distance (**Figure 9A**). At this stage, only PTH-proline is well separated from the other derivatives. After evaporation of the methylene chloride, the second development was performed with methylene chloride–isopropanol (99 : 1 for 10 min with a 7.5 cm development distance). **Figure 9B** illustrates that five amino acid derivatives can be identified. The third consecutive development was made in the same way as the second (**Figure 9C**). The fourth step was obtained by development with methylene chloride–isopropanol (97 : 3) for 10 min (**Figure 9D**). The most polar PTH-amino acid derivatives are not resolved. Their resolution was achieved in the fifth step with ethyl acetate–

acetonitrile–glacial acetic acid (74.3 : 25 : 0.7); only two derivatives (GLU, GLN) are not separated (**Figure 9E**).

The separation efficiency of conventional multiple development can be further improved by moving the solvent entry to a higher position on the chromatographic plate for each successive development. **Figure 10** shows the separation of a mixture of six

oestrogens on silica gel plates, 5 × 10 cm with a mobile phase of cyclohexane–ethyl acetate (3 : 1, v/v). The chromatograms were scanned at 280 nm. The poorest separation was obtained with simple multiple chromatography (Figure 10A); seven 7 cm developments with fixed solvent entry position at the origin of the plate were used. Separation was improved using multiple development with incrementing times (or distances) of development.

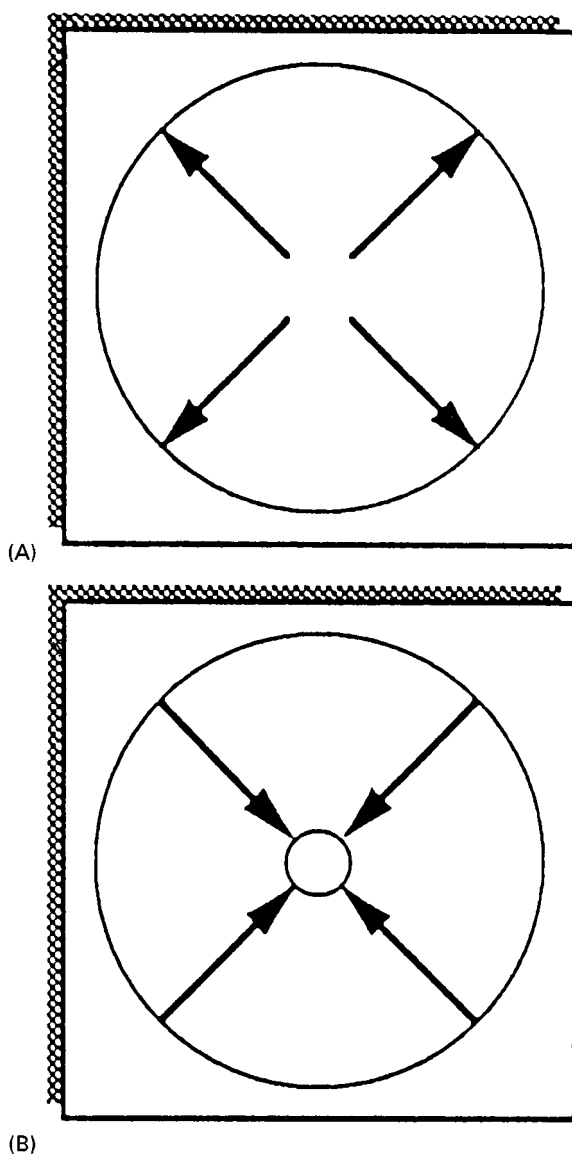

Figure 13 (A) Circular and (B) anticircular development. (Reproduced with permission from Bauer K, Gros L and Saur W (1991) *Thin Layer Chromatography – An introduction*, p. 36. Heidelberg: Hüthig Buch).

Figure 10B shows the chromatogram using nine developments with an incremental increase of the time of each successive development according to the sequence 5, 6, 7, 8, 9, 10, 12, 13, 14 min. However, the best separation was achieved with an incremental increase in the development time, as above, and a variable solvent entry position (0.5 cm below the slowest zone in each development; Figure 10C).

In two-dimensional development the sample is spotted at the corner of the chromatographic plate and developed with the first eluent (in the first direc-

tion). After this development, the eluent is evaporated from the plate; the spots are positioned along the edge of the chromatographic plate. The plate is then rotated through 90° and the next development is performed with the second eluent from the edge with the separated spots of the first development towards the opposite edge. The mixture can be redistributed on the entire plate surface if both eluents (or chromatographic systems) show a dramatic change in selectivity. An example of this mode of separation is shown in Figure 11. Twenty DNP-amino acids were separated using a reversed-phase layer. The sample volume was $0.2\text{--}0.3\ \mu\text{L}$. The spots were visualized in UV light (360 nm with a dried plate or 254 nm when wet). The migration distance was 6 cm. The separations were carried out at 25°C using a Desaga thermostating chamber. The elution in the first direction was performed with hexane–ethyl acetate–acetic acid (80 : 18 : 2) and in the second direction with 1 mol L^{-1} ammonia + 30% potassium chloride in 60% methanol.

Another variant of two-dimensional development is the separation of four samples on one plate instead of one sample on one plate. Figure 12 shows the application of this method to the separation of hormones. The silica gel plate, $10 \times 10\text{ cm}$, is divided into four sample zones and four reference zones, as shown in Figure 12A. The four samples (S1, S2, S3, S4) are spotted at each corner of the plate and the reference solutes on the four reference zones (R1, R2, R3, R4). The plate is introduced into a horizontal DS-chamber (Chromdes) or a linear developing chamber (Camag), which allows the development of the plate from two opposite directions simultaneously with eluent

1 (heptane–diethyl ether–dichloromethane, 4 : 3 : 2) in two opposite directions: 1A, 1B. When both eluent fronts reach the zone R2–R4 the plate is removed from the chamber and dried. Afterwards the plate is turned through 90° and developed with eluent 2 (chloroform–ethanol–benzene, 36 : 1 : 4) in two opposite directions: 2A and 2B. Before each development the chamber is saturated for 3 min with eluent vapour. After development the plate is sprayed with 5% sulfuric acid in ethanol, dried and heated for

5 min at 100°C. The chromatogram shown in Figure 12B was observed in visible or UV light (366 nm).

Radial Development

There are two principal modes of radial development: circular and anticircular. In circular development the mobile phase is supplied at the centre of the chromatographic plate and eluent traverses towards the periphery (Figure 13A). The samples are spotted around the entry position of the mobile phase or are introduced (injected) into the stream of eluent just before its entry on the plate.

A very simple and probably the oldest application of circular development is the spot test, which is used for finding a suitable mobile-phase composition for TLC and HPTLC systems. The sample mixture is spotted on the adsorbent layer in several places and into the centre of each spot different solvents (pure or

occasionally mixtures chosen from the eluotropic series) are applied by a capillary or microsyringe. Then circular development provides ring chromatograms. Different solvents result in various shapes of chromatograms (Figure 14). If a solvent of too low an eluent strength is used, the sample does not move. On the other hand, the sample forms a compressed ring on the outer circle of wetted adsorbent when too strong a solvent is applied. Concentric rings on the entire wetted surface appear when solvents of suitable eluent strength and selectivity are used.

Circular development is also applied to analytical separations. Figure 15a shows an example of sugar separation obtained by circular development. A high performance TLC plate was developed in a U-chamber (Camag) with a solution of *n*-butanol–acetic acid–water (5 : 4 : 0.25). The samples were spotted around the central point of the plate at the entry position of the solvent. Visualization was performed

Figure 18 Anticircular chromatogram. (Reproduced with permission from Fenimore DC and Davis CM (1981) High performance thin-layer chromatography. *Analytical Chemistry* 53: 252A.)

with sulfuric acid containing naphthoresorcinol by spraying or dipping with this reagent and heating at 100°C for 5 min. The spots near the origin are symmetrical and compact but those further away are more compressed and elongated at right angles to the direction of development. The sample was also separated in the same chromatographic system, but using linear development on a 10 × 10 cm plate (Figure 15B).

If the sample is introduced in the mobile-phase stream, then separated bands form concentric rings on the chromatographic plate, as shown in Figure 16. This circular chromatogram demonstrates the separation of lipophilic dyes on a silica gel 60 F₂₅₄ high performance TLC pre-coated plate, 10 × 10 cm (E. Merck) with a mobile phase of hexane–chloroform–NH₃, 70 : 30; the distance of development (from entry position of solvent to eluent front) = 30 mm in a Camag U-chamber.

In the anticircular mode of development the mobile phase enters around the entire periphery of the adsorbent layer which is usually formed as a circle by scraping unwanted adsorbent from a square plate.

The samples are applied on an outer circular starting line and development proceeds from the periphery of this circle layer to its centre (Figure 13B). This mode of development can be performed with a Camag anticircular U-chamber, shown in Figure 17.

Anticircular chromatography is seldom applied in practice. An example of a chromatogram obtained by this mode of development is given in Figure 18. The spots are compact near the origin and elongated in the direction of the mobile-phase migration.

Conclusions

Conventional modes of chromatogram development are often applied in analytical practice for both qualitative and quantitative purposes. The most popular among the modes described is linear development. There are several reasons which contribute to this situation, including a simple operation procedure and low cost and time of analysis per sample. These features will still determine a future use of the modes in the analytical practice of planar chromatography in spite of increasing interest in the application of automated and forced-flow development.

Modes of Development: Forced Flow, Overpressured Layer Chromatography and Centrifugal

S. Nyiredy, Research Institute for Medicinal Plants, Budakalász, Hungary

Introduction

Forced-flow planar chromatographic separation can be achieved by application of external pressure (over-

pressured layer chromatography – OPLC), an electric field, or centrifugal force (rotation planar chromatography – RPC). Figure 1 shows schematically the superior efficiency of forced-flow techniques by comparing their analytical performance with those of classical thin-layer chromatography (TLC) and high performance thin-layer chromatography (HPTLC). Forced-flow planar chromatography (FFPC) tech-

Figure 1 Comparison of the efficiency of analytical TLC and HPTLC chromatographic plates when used with capillary action and forced-flow planar chromatography (FFPC). N_{US} , normal unsaturated chamber; UM, ultramicrochamber; N_S , normal saturated chamber.

niques enable the advantage of optimum mobile phase velocity to be exploited over almost the whole separation distance without loss of resolution. This effect is independent of the type of forced flow.

Although FFPC can be started with a dry layer, as in classical TLC, the forced-flow technique also enables fully online separation in which the separation can be started on a stationary phase equilibrated with the mobile phase, as in high performance liquid chromatography (HPLC). The following FFPC combinations of the various offline and online operating steps are feasible:

- Fully offline process: the principal steps, such as sample application, separation, and detection are performed as separate operations
- Offline sample application and online separation and detection

- Online sample application and separation and off-line detection
- Fully online process: the principal steps are performed as nonseparate operations.

Overpressured Layer Chromatography

In addition to capillary action, the force driving solvent migration in OPLC is the external pressure. Depending on the desired mobile-phase velocity, operating pressures up to 50 bar can currently be used. In OPLC (Figure 2) the vapour phase is completely eliminated; the chromatographic plate is covered with an elastic membrane under external pressure, thus the separation can be performed under controlled conditions. The absence of any vapour space must

Figure 2 Schematic diagram of online OPLC. 1, Support block; 2, chromatoplate; 3, support plate; 4, spring; 5, cassette system for fixing the chromatoplate between two Teflon layers; 6, Teflon layer; 7, Mobile phase inlet; 8, mobile phase outlet; 9, hydraulic system.

be considered in the optimization of the solvent system, especially in connection with the disturbing zone and multifront effect, which are specific features of the absence of a vapour phase (see section entitled 'Elimination of Typical Problems With Use of OPLC').

Principle of Multi-Layer OPLC (ML-OPLC)

OPLC is suitable for the development of several chromatographic plates simultaneously if the plates are specially prepared. With this multi-layer technique, many samples can be separated during a single chromatographic run. By connecting chromatographic plates in parallel (Figure 3) more HPTLC plates can be developed simultaneously. By circular OPLC, 360 samples of plant extracts can be separated in 150 s. The rapidity and/or efficiency of the OPLC separation of complex samples can be increased by use of ML-OPLC, in which the same or different types of stationary phase can be used for the development of more chromatographic plates.

Principle of Long-Distance OPLC (LD-OPLC)

Long-distance OPLC is a multi-layer development technique with specially prepared plates. Similar to the preparation of layers for linear OPLC development, all four edges of the chromatographic plates must be impregnated with a polymer suspension. The movement of the eluent with a linear solvent front can be ensured by placing a narrow plastic sheet on the layer or scraping a narrow channel in the sorbent for the solvent inlet. Several plates are placed on top of each other to ensure the long running distance. A slit is cut at the end of the first (upper) chromato-

graphic plate to enable the mobile phase to travel to a second layer. Here the migration continues until the opposite end of the second layer, where solvent flow can be continued to the next adjacent chromatographic plate, or the eluent is led away (Figure 4A) if migration is complete. Clearly, on this basis a very long separation distance can be achieved by connecting one plate to another.

Figure 4B shows a typical combination of the same type of chromatographic plate (homoplates). In the arrangement presented, the upper plate has an eluent inlet channel on one side and a slit on the other side for conducting the mobile phase to the next plate. The slit (width approximately 0.1 mm) can be produced by cutting the layer; this enables ready passage of the mobile phase and individual samples without mixing. The cushion of the OPLC instrument is applied to the uppermost layer only, and each plate presses the sorbent layer below. As a consequence of this, glass-backed plates can be used in the lowest position only. The illustrated fully off-line separation is complete when the ' α ' front (the front of the first solvent in an eluent solvent mixture) of the mobile phase reaches the end of the lowest plate.

The potential of the connected layers can be increased by use of different (hetero) stationary phases during a single development; this is shown in Figure 4C, in which the different sorbents are marked with various shades of gray. The eluate can, furthermore, be led from the lower plate, similarly to the way in which it was led in. This gives the possibility of online detection. For this fully online operating mode all layers placed between the highest and lowest plates must have 1 cm cut from the

Figure 3 Schematic diagram of multi-layer OPLC (ML-OPLC). (A) Linear one-directional development; (B) linear two-directional development; (C) circular development.

length of the plate, to leave a space for mobile phase outlet.

Analytical OPLC Separations

In OPLC, the most frequent modes of development are linear one- and two-directional (Figure 5A,B). Linear OPLC, however, requires a special chromatographic plate sealed along the edge, by impregnation, to prevent the solvent from flowing off the layer.

The advantage of circular development, in which the mobile phase migrates radially from the centre of the plate to the periphery, is well known for the separation of compounds in the lower R_F range,

where circular development gives 4–5 times greater resolution. The separating power of circular development is better exploited if the samples are spotted near the centre. As the distance between the mobile-phase inlet and sample application increases, the resolution begins to approach that of linear development. No preparation of the plate is necessary for offline circular OPLC (Figure 5C); for online circular OPLC (Figure 5D) a segment-shaped region must be isolated by removing the surrounding adsorbent and impregnating its edges.

Figure 4 Schematic diagram of long-distance OPLC (LD-OPLC). (A) Principle of the method; (B) fully offline LD-OPLC using homolayers; (C) fully online LD-OPLC using heterolayers.

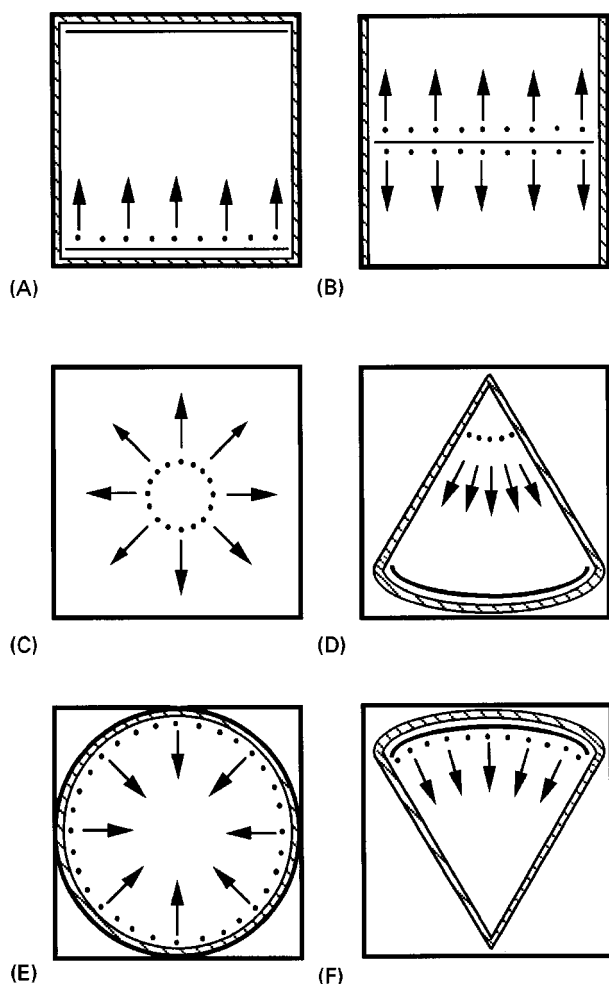

Figure 5 Development modes in analytical OPLC using 20 cm \times 20 cm HPTLC chromatographic plates. (A) Linear unidirectional; (B) linear two-directional; (C) circular with 8 cm development distance; (D) circular with 18 cm development distance, or online circular; (E) anticircular; (F) anticircular with 18 cm development distance, or online anticircular.

Conventional offline anticircular separation (Figure 5E) is rather difficult to perform because of the large perimeter of the mobile-phase inlet (ca. 60 cm for a 20 cm \times 20 cm plate). Fully offline and online anticircular separations can, however, be performed over a separation distance of 18 cm, after suitable preparation of the plate by isolating a segment of the layer (by scraping) and sealing the isolated segment with polymer suspension (Figure 5F).

In linear OPLC the maximum separation distance is 18 cm for 20 cm \times 20 cm chromatographic plates. In offline circular OPLC the maximum separation distance is 10 cm, and only one sample can be analysed. If the distance between the mobile phase inlet and the point of sample application is 2 cm, a separation distance of 8 cm can be achieved; this enables application of more samples.

Micropreparative OPLC Separations

Instrumental methods such as OPLC increase preparation time and costs but also significantly improve efficiency. As a rule of thumb, if the sample contains more than five substances, up to 10 mg of sample can be separated by micropreparative OPLC with linear development on an HPTLC plate. This can be increased five-fold by use of five HPTLC plates and a multi-layer technique; thus preparative amounts can be separated by means of a micropreparative technique. If the sample contains fewer than five substances, the amounts can be increased to 50 mg on a single chromatographic plate. Linear online OPLC is preferable if the structures of compounds to be separated are similar. The circular offline technique can be used if the separation problem is in the lower R_F range.

Probably the most important application of layer switching is in sample clean-up based on a new connection between the layers. A special clean-up effect, sample application and reconcentration, can be achieved simultaneously as shown in Figure 6A, in which the upper plate serves for clean-up. Needless to say, these steps can both be performed in fully offline or fully online operating modes, or in freely chosen combinations of different offline and online steps.

The connection illustrated in Figure 6B is an arrangement suitable for a larger amount of complex sample. In this example micropreparative development can be performed on pre-coated fine particle-size analytical plates. The mobile-phase inlet system with the slits is analogous to that for multi-layer development. In the example illustrated, the direction of mobile-phase migration is the same for each pair of plates. The scraped channels are located at the beginning of the upper two layers and the slits are located at the ends of the adsorbent layers. On reaching the end of the first pair of plates the mobile phase passes through to the adjacent pair of layers. Suitable location of channels and slits ensures mobile phase transport through the whole system. The collector channel at the end of the lowest plate leads the eluate to the outlet.

Preparative OPLC Separations

Whether or not the use of OPLC for preparative separation is necessary depends on the kind of sample to be separated. The potential of linear online OPLC on 20 cm \times 20 cm plates with a separation distance of 18 cm as a preparative method is considerable. Because the average particle size of pre-coated preparative plates is too large, not all the advantages of this method can yet be realized. Generally, preparative online OPLC can be used for separation of 6–8 compounds in amounts up to 300 mg.

(A)

Elimination of Typical Problems with Use of OPLC

It is of practical importance to summarize the most important distorting effects which arise in OPLC and to describe means of eliminating these problems.

Linear separations require specially prepared chromatographic plates with chamfered edges that are impregnated with a suitable polymer suspension, to prevent solvent leakage at overpressure. For proper preparation of the chromatographic plate, the surface from which the stationary phase has been scratched must be fully cleaned from particles. If this is not achieved, a narrow channel may be formed under the

polymer suspension, resulting in faster migration of part of the mobile phase, because of lack of layer resistance; the mobile phase then re-enters further along the plate ('break-in effect' as shown in Figure 7A). This reduces the value of the separation, at least at the edge(s) of the layer.

If the area impregnated is too wide, i.e. the edges of the stationary phase covered by the polymer suspension are wider than approximately 1 mm, the 'meniscus effect' can occur (see Figure 7B). As a

(A)

(B)

(C)

Figure 7 Elimination of typical problems in OPLC. (A) 'Break-in effect' – a consequence of improper impregnation of the chromatographic plate; (B) 'meniscus effect' – a consequence of improper impregnation of the chromatographic plate; (C) lack of the appropriate inlet pressure for linear separation.

consequence of this effect – which occurs either in the concave or convex form, depending on the physical properties of the solvents used – the eluent flows more slowly or more quickly on both edges of the chromatographic plate, again distorting quantitative results.

Before starting the separation with the optimized mobile phase, the mobile phase inlet valve is closed and the eluent pump is started to establish an appropriate solvent pressure. The separation is then started by opening the inlet valve; this ensures the rapid distribution of the mobile phase in the inlet channel necessary for linear migration of the mobile phase. If the inlet pressure is too low and the mobile phase does not fill the inlet channel totally, the start of the separation is similar to that for circular development; the distorted linear separation obtained is shown in Figure 7C. No preparation of the plate is needed for offline circular separations.

If multi-component mobile phases are used in unsaturated TLC, the fronts arising from the components can have a decisive influence on the separation. This effect can be substantial in OPLC; the secondary fronts appear as sharp lines because no vapour phase is present. Compounds of the mixture migrating with one of the fronts form sharp, compact

zones whereas tailing or fronting can be observed for compounds migrating directly in front of or behind the α front. With multi-component mobile phases the 'multi-front effect' can appear in two forms. In the first (Figure 8A), one or more fronts can occur between compounds to be separated. In the second, all the compounds to be separated migrate behind the lowest front (Figure 8B), and the fronts do not influence the separation. As the position of the fronts is constant, if the chromatographic conditions are constant, possibly undesirable effects of the multi-front effect can be monitored and taken into account by applying the spots or bands stepwise. Thus for linear separations the sample is applied at different distances ($s = 1, 2, \dots, n$) from the mobile phase inlet channel (Figure 8C). In circular OPLC the samples are applied at points on concentric circles (or rings) with their centres at the mobile phase inlet (Figure 8D). Quantitative evaluation is usually made more difficult, but not impossible, by the multi-front effect, because the phantom peaks formed at the fronts can be measured densitometrically in the substance-free zones at the sides of the chromatographic plates, and thus the values are taken into account. It must be mentioned that the multi-front effect also has a

Figure 8 'Multi-front effect' – a consequence of the use of multicomponent mobile phases. (A) The fronts occur between the compounds to be separated; substances migrating with one of the fronts form sharp, compact zones; (B) the compounds to be separated all migrate behind the lowest front, so the fronts do not influence the separation; (C) diagonal application of the samples (as bands) for linear separations to check the place of the different fronts; (D) eccentric application of the samples (as spots) for circular separations to check the place of the different fronts.

Figure 9 The 'disturbing zone' as a consequence of different air/gas volume ratios adsorbed by the surface of the stationary phase and dissolved in the eluent.

positive effect in preparative separations, because compounds that migrate with α front can be eluted in a very small amount of mobile phase.

If OPLC separation is started with a dry layer, distorted substance zones can sometimes be observed in different R_F ranges, depending on the mobile phase used and the velocity of the mobile phase. This effect appears during the chromatographic process as a zig-zag zone across the width of the plate, perpendicular to the direction of development as a result of the different refractive indices of the solvents in front of and behind this zone. This phenomenon, termed the 'disturbing zone', is depicted in **Figure 9**. The extent of this phenomenon depends on the interrelationship between gas physically bound to the surface of the sorbent and gas molecules dissolved in the mobile phase. Because modification of the location of the 'disturbing zone' is possible within a very narrow range, the only solution to this problem is to conduct a prerun. For separation of nonpolar compounds this can be performed with hexane; for separation of polar substances the prerun can also be performed with hexane or with any component of the mobile phase in which the components are unable to migrate. The selection of this solvent might be considered during optimization of the mobile phase.

Advantages of OPLC

The advantages of the different OPLC methods are summarized as follows:

1. All commercially available chromatographic plates can be used, irrespective of their size and quality; stationary phases prepared from smaller particles can be used without loss of resolution as a result of the overpressure.
2. Mobile phases optimized in unsaturated analytical TLC can be transferred after a suitable prerun.
3. Circular development can be performed without special preparation of the plates; for linear and anticircular development specially prepared plates are necessary.
4. Many samples (up to 72) can be separated rapidly on a single analytical plate and evaluation can be performed densitometrically.
5. Multilayer OPLC is applicable for offline separation of many (up to 360) samples, again with densitometric evaluation.
6. The separation time is relatively short and scale-up for preparative work is simple.
7. All linear separation methods (analytical, micro-preparative, preparative) are online; removal of the separated compounds by scraping off the layer is unnecessary.
8. Online determination of a single analytical sample on fine particle-size analytical plates, and online micro-preparative and preparative separations can be recorded with a flow through detector.
9. Online preparative separation of 10–500 mg samples can generally be performed in a single chromatographic run.
10. The development distance can be easily increased by use of long-distance OPLC.
11. Combination of different adsorbents can be used in long-distance OPLC so that each part of a complex mixture can be separated on a suitable stationary phase.

Rotation Planar Chromatography

The term 'rotation planar chromatography' (RPC) – irrespective of the type and quality of the stationary phase – embraces analytical, offline micro-preparative and online preparative forced-flow planar chromatographic techniques in which the mobile phase migrates mainly with the aid of centrifugal force, but also by capillary action. The centrifugal force drives the mobile phase through the sorbent from the centre to the periphery of the plate. The mobile phase velocity may be varied by adjustment of the speed of rotation.

The different RPC techniques can be classified as normal chamber RPC (N-RPC), micro chamber RPC (M-RPC), ultramicro chamber RPC (U-RPC) and column RPC (C-RPC); the difference lies in the size of the vapour space, an essential criterion in RPC. For analytical separations many samples can be applied. For micro-preparative and preparative purposes only one sample is applied as a circle near the centre of the rotating stationary phase. The separations can be performed either in the offline or online mode. In the latter, the separated compounds are eluted from

Figure 10 Principles of RPC. (A) Fully offline analytical separation; (B) fully offline micropreparative separation; (C) fully online preparative separation.

the stationary phase by the centrifugal force and collected in a fraction collector (**Figure 10**). All methods can be used for online preparative separations; M-RPC and U-RPC can also be used for analytical and offline micropreparative separations.

Principles of N-RPC, M-RPC and U-RPC

In N-RPC the layer rotates in a stationary chromatographic chamber; in M-RPC – which uses a co-rotating chromatographic chamber – the vapour space is reduced and variable; in U-RPC the layer is placed in the co-rotating chamber from which the vapour space has been almost eliminated. A schematic drawing of preparative M-RPC is shown in **Figure 11**; the layer thickness is approximately 2 mm. When the ultra-microchamber is used, the chromatographic layer is thicker (4 mm); the quartz cover plate is placed directly on the layer so there is almost no vapour space. In N-RPC the quartz plate is removed; this results in a large vapour space.

In all three methods circular development is always used for preparative separations. The sample is applied near the centre of the circular layer, and the

mobile phase is forced through the stationary phase from the centre to the outside of the plate (rotor). The separated compounds are eluted from the layer by centrifugal force and collected in a fraction collector. A detector and recorder can be incorporated before the collector.

M-RPC and U-RPC can be used not only for online preparative separations, but also for analytical and offline micropreparative purposes. Excellent resolution is obtained on HPTLC plates.

Principles of S-RPC

For difficult separation problems a special combination of circular and anticircular development can be performed with the sequential rotation planar chromatography (S-RPC). The mobile phase can be introduced onto the plate at any desired place and, time. In S-RPC the solvent application system – a sequential solvent delivery device – works by centrifugal force (circular mode) and with the aid of capillary action against the reduced centrifugal force (anticircular mode). Generally the circular mode is used for the separation, the anticircular mode for pushing the

Figure 11 Schematic diagram of preparative M-RPC. 1 = lower part of the stationary chamber, 2 = collector, 3 = motor shaft with the rotating disc, 4 = glass rotor, 5 = stationary phase, 6 = quartz glass cover plate, 7 = mobile phase inlet, 8 = eluent outlet.

Figure 12 Schematic diagram of preparative C-RPC. 1 = lower part of the stationary chamber, 2 = collector, 3 = motor shaft with the rotating disc, 4 = rotating planar column, 5 = stationary phase, 6 = quartz glass cover plate, 7 = mobile phase inlet, 8 = eluent outlet.

substance zones back to the centre with a strong solvent (e.g. ethanol). After drying the plate with nitrogen at a high rotation speed, the next development with another suitable mobile phase can be started. By combination of the two modes of operation the separation pathway in S-RPC becomes theoretically unlimited.

Principles of C-RPC

In column RPC (see Figure 12) there is no vapour space – the stationary phase is placed in a closed circular chamber (column). The volume of stationary phase stays constant along the separation distance and the flow is accelerated linearly by centrifugal force, hence the name ‘column’ RPC. Because a closed system is used, there is no vapour space and any stationary phase can be used – fine particle size, with or without binder. The rotating planar column has a special geometric design described by eqn [1]

$$h = \frac{K}{(a + br + cr^2)} \quad [1]$$

where r = radius of the planar column, h = actual height of the planar column at radius r , a , b , c , and K = constants.

This design eliminates the extreme band-broadening which occurs normally in all circular development techniques, and so combines the advantages of both planar and column chromatography.

Analytical RPC Separations

In analytical M-RPC there is a vapour space (1 or 2 mm) between the chromatographic plate and the quartz glass cover plate. In analytical U-RPC a soft crepe rubber sheet is placed underneath the analytical plate so that vapour space between the layer and the quartz cover plate is almost eliminated.

In analytical RPC (M-RPC and U-RPC) three development modes are available and the separation distance and number of samples depend on which mode is used. 20 cm × 20 cm plates can be introduced directly into the instrument. In circular mode (Figure 13A) the most commonly used, up to 72 samples can be applied to an HPTLC plate as spots; the separation distance is usually 8 cm. Despite the centrifugal force, the mobile phase direction of flow can be linearized (linear development mode) by scraping channels in the layer (Figure 13B); this reduces the number of samples. The anticircular mode can also be employed with special preparation of the analytical plate (Figure 13C). Although the solvent is delivered

Figure 13 Development modes in analytical RPC on 20 cm × 20 cm HPTLC plates. (A) Circular; (B) linear; (C) anticircular.

at the centre of the plate, in anticircular mode the amount of stationary phase available during development is reduced according to a quadratic relationship by preparation of the layer.

Micropreparative RPC Separations

A mixture of components (5–15 mg) can be applied in the form of a ring near the centre of a single analytical HPTLC plate for isolation of relatively pure compounds by use of U-RPC or M-RPC. The operating process is similar to that used for analytical separations, with the difference that only one sample is applied. Continuous development is possible if a ring of radius 9.8 cm is scraped from the stationary phase, to ensure the regular migration of the mobile phase after it has reached the outskirts of the plate. When the first compounds of interest reach this ring, the separation must be stopped, and either with a stationary rotor or at a rotation speed of 100 rpm the separated components can be scraped out and then the remaining substances can be eluted by the usual procedures, similar to preparative TLC. The separation of ultraviolet (UV)-active compounds can be monitored with a UV lamp during the separation.

Preparative RPC Separations

Because all preparative RPC separations are performed online and no removal of the zones by scratching is necessary, the separation efficiency for the last eluting compounds even increases during the run.

Because M-RPC and U-RPC can be used not only for online preparative separations, but also for analytical purposes, direct scale-up is possible for both analytical methods. From TLC separations using unsaturated or saturated chromatographic tanks, the mobile phase can be transferred via analytical U-RPC and M-RPC to preparative U-RPC and M-RPC, respectively, if the solvent strength and selectivity are kept constant. For scale-up the sample may be applied as a circle to a 20 cm × 20 cm analytical TLC plate and the amount of sample can be increased stepwise in subsequent separations. The adverse effects of different particle sizes and separation distances in the analytical and preparative methods almost cancel each other, so only layer thickness has to be considered in the scale up procedure. The mobile phase flow rate must be adapted to preparative separation, so that the migration of the α front is as fast as in the analytical separation.

Elimination of Typical Problems in RPC

In RPC extra evaporation of the mobile phase occurs owing to the rotation of the chromatographic plate;

this can have undesirable effects. In analytical RPC these are the 'surface effect' and the 'effect of the standing front'. The optimum velocity of rotation depends on the particular separation problem. The flow rate is limited by the amount of solvent that can be kept in the layer (layer capacity) without floating over the surface. The greater the amount of solvent applied, the higher the rotation speed must be to keep the mobile phase within the layer. The parameters, rotation speed, perimeter of solvent application and development mode must be considered when setting the pumping speed, otherwise the mobile phase flows over the top of the applied sample and the layer ('surface effect') distorting the separation. A standing front can occur if after a certain time, the well-separated compounds mix back again because the α front becomes stationary owing to the amount of mobile phase evaporating becoming equal to the amount being delivered. When N-RPC is used for preparative purposes, the 'effect of the change of mobile phase composition' is a typical negative effect, which has to be considered during the optimization of the mobile phase.

Advantages of RPC

The advantages of the different RPC methods, can be summarized as follows:

1. Depending on the properties of the compounds to be separated, the effect of the vapour space, and thus the extent of saturation of the chromatographic system, can be selected freely.
2. All commercially available stationary phases can be used, irrespective of their size and quality; smaller particle size stationary phases can be used without loss of resolution because of the centrifugal force.
3. Mobile phases optimized in saturated or unsaturated analytical TLC, or in HPLC, can be transferred to the various RPC methods.
4. All three basic modes of development (circular, linear, and anticircular) and their combinations can be used for analytical separations.
5. For analytical purposes up to 72 samples can be applied to a single analytical plate, and densitometric quantification can be performed *in situ* on the plate.
6. The separation time is relatively short and scaling up to preparative methods is simple.
7. All preparative methods are online, no scratching out of the separated compounds is necessary, and the preparative separation can be recorded with a flow-through detector.
8. Because of the theoretically unlimited separation distance, the separation power can be increased

Table 1 Comparison of the different analytical and preparative FFPC (OPLC and RPC) methods

significantly by employing the sequential technique.

9. On line preparative separation of 50–500 mg samples can generally be applied in a single chromatographic run.

Comparison and Outlook of FFPC Methods

The various OPLC and RPC techniques are compared in Table 1. Study of the data shows that OPLC is an excellent technique for analytical separations and that RPC is more ideally suited as a preparative method for isolation of compounds from biological matrices.

The advantage of combining online and offline separations and two-dimensional development can also be exploited in OPLC. The advantage of multiple development methods is the possibility of analytical RPC separations. A realistic means of increasing the efficiency of the planar chromatography of complex samples is the use of long-distance OPLC for analytical separations and sequential RPC for preparative purposes. Working with multi-layer OPLC, the rapidity of the separation can increase significantly, providing new vistas in screening and genetic work.

FFPC techniques will open up a new field of planar chromatography, particularly in the separation of complex samples. It is expected that future research will concentrate on the positive effects (applied pressure in OPLC and higher centrifugal force in RPC) of forced flow. As a consequence, smaller particle size, narrower distribution range, and spherical stationary phases will be needed to achieve maximum resolution.

Preparative Thin-Layer (Planar) Chromatography

Introduction

Preparative planar (thin-layer) chromatography (PPC) is a liquid chromatographic technique performed with the aim of isolating compounds, in amounts of 10–1000 mg, for structure elucidation

(mass spectrometry (MS), nuclear magnetic resonance (NMR), Infrared (IR), ultraviolet (UV) etc.), for various other analytical purposes, or for determination of biological activity. PPC is a valuable method of sample purification for preparative purposes and isolation. The scope for modifying operating parameters such as the vapour space, development mode and for offline sample application is enormous in planar chromatography.

In classical PPC the mobile phase migrates by capillary action, whereas if forced-flow PPC (FFPPC) is

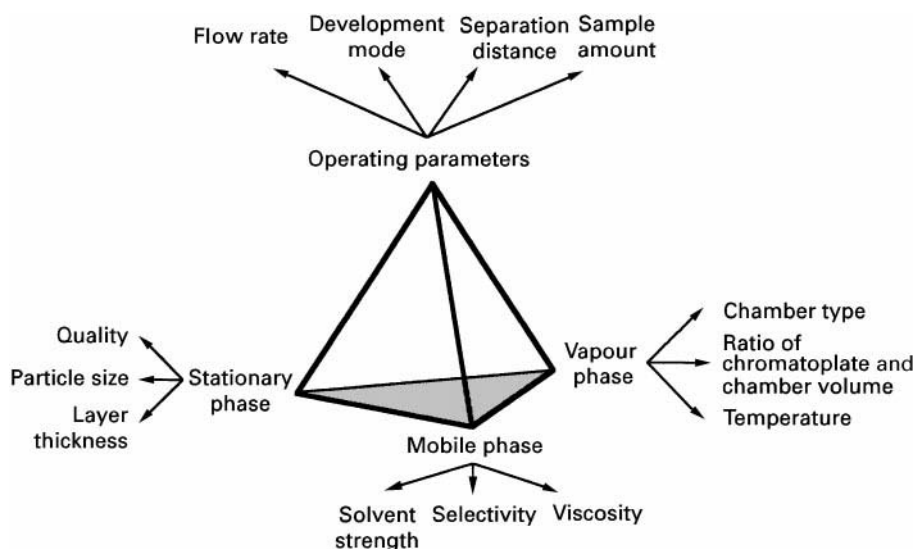

Figure 1 The principal factors affecting preparative layer chromatography.

used, migration of the mobile phase is also promoted either by application of external pressure (overpressured layer chromatography (OPLC)) or by use of centrifugal force (rotation planar chromatography (RPC)). (For more information see the previous entry Modes of development: Forced flow, OPLC and centrifugal.) The enhanced efficiency obtained by use of the optimum mobile phase velocity is independent of layer thickness and of the type of forced flow applied.

Parameters of PPC Separation

One of the most important experimental variables in PPC is the vapour space, because the separation pro-

cess occurs in a three-phase system of stationary, mobile, and vapour phases, all of which interact until equilibrium is reached. The most important factors which might influence a PPC separation are shown in Figure 1.

Stationary Phase

Although alumina, cellulose, and C_2 and C_{18} reversed-phase pre-coated preparative plates are available, silica has been most widely used by far. The silica materials commonly used for PPC have coarse particle sizes (average $\sim 25 \mu\text{m}$) and their distribution range (between 5 and $40 \mu\text{m}$) is also wide; Figure 2

Figure 2 Particle sizes and particle-size distributions of silica stationary phases.

compares the quality of pre-coated analytical (TLC and HPTLC) and preparative plates, and that of silica for TLC. The advantage of making one's own preparative plates is that any desired thickness (< 10 mm) or layer composition (incorporation of salts, buffers, etc.) becomes feasible. Pre-coated $20\text{ cm} \times 20\text{ cm}$ or $20\text{ cm} \times 40\text{ cm}$ preparative plates with layer thicknesses 0.5, 1.0, 1.5, and 2 mm have the advantage of much higher reproducibility. It is generally accepted that higher resolution can be achieved on a thinner preparative layer (0.5–1.0 mm) and the resolution is much more limited on a higher capacity (1.5–2 mm) layer. The loading capacity of a preparative layer increases with the square root of the thickness, practically without loss of separating power so that as a rule of thumb, the loading capacity of a 0.5 mm layer is approximately half that of a 2 mm layer.

Preparative plates are commercially available with or without preadsorbent zones. The preadsorbent zone (generally 4 cm width) serves as a holding zone for the sample until development begins. Soluble compounds migrate with the mobile phase front through the preadsorbent zone and are concentrated in a narrow band as they enter the chromatographic layer, thus improving the resolution. The materials used to manufacture these concentrating zones are kieselguhr or inert silica. Resolution can also be significantly increased by using a layer-thickness gradient that contains a wedge-shaped silica layer ranging in thickness from 0.3 mm at the bottom to 1.7 mm at the top, with an adjacent 700 μm preadsorbent layer for sample application. The cross-sectional area traversed by the mobile phase front increases during migration through the tapered layer, so the cross-sectional flow per unit area is highest at the bottom of the layer and decreases towards the solvent front. As

a result the lower portion of a zone moves faster than the upper portion, keeping each component focused in a narrow band. Theoretical separations on a preparative plate, without and with preadsorbent, and compared with a tapered plate, are depicted in Figure 3A–C. The improved resolution as a result of the greater local mobile phase velocity clearly suggests the wider use of a preadsorbent layer or a layer-thickness gradient if at all possible.

Mobile Phase

The separations can be started in saturated or unsaturated chromatographic tanks. However, on starting the separation in an unsaturated chamber the chromatographic tank becomes saturated during the development because of the long separation time (1–2 h). If saturated chromatographic chambers are used, the optimized analytical mobile phase may be transferred unchanged to PPC. Because the particle sizes and size distribution of sorbents for preparative purposes are larger, and the plates are overloaded with the compounds to be separated, inferior separation is invariably achieved on preparative plates. This means that a successful preparative separation will need an optimized mobile phase.

The 'PRISMA' mobile phase optimization system enables not only optimization of solvent strength and mobile phase selectivity, but also transfer of the optimized mobile phase between the different planar chromatographic techniques. The system is based on the solvent classification by Snyder, who classified more than 80 solvents into eight groups for normal phase (NP) chromatography according to their properties as proton acceptors (X_a), proton donors (X_d), and their dipole interactions (X_n). Because

Figure 3 Comparison of separations on different preparative plates. (A) Pre-coated chromatographic plate without concentrating zone, (B) pre-coated chromatographic plate with concentrating zone, (C) pre-coated chromatographic plate with layer-thickness gradient.

$X_a + X_d + X_n = 1$, the solvents can be characterized by two of them (e.g. X_a and X_d), and so a new definition was introduced – the individual selectivity value (S_v), which is the ratio of X_a to X_d . The individual solvent strengths (S_i), selectivity values, and viscosities of the solvents most often used for normal phase PPC, are listed in Table 1.

For characterization of multi-component mobile phases the total solvent strength (S_T) can be defined as the sum of the S_i of the components, weighted by multiplication by their volume fraction. The total selectivity factor (S_V) can be also calculated similarly to the S_T value.

The volatility of the individual solvents must be also considered during the optimization process, otherwise several problems can arise in subsequent steps (elution of the compound from the stationary phase, evaporation of the solvent). It also precludes the use of, e.g. acetic acid as a component of the preparative mobile phase, because of the possibility of chemical degradation during concentration of the isolated compounds. Multicomponent mobile phases should not be used repeatedly, whereas single-solvent mobile phases can be used repeatedly until they become contaminated.

Figure 4 shows the transfer possibilities of the mobile phase, where thick lines indicate direct transfers. The thin lines indicate transfers which are also possible, but the solvent strength and selectivity must generally be changed. The dashed lines indicate direct transfer possibilities for fully online separation processes.

Table 1 Selected solvents for normal phase PPC separation

Selectivity group	Solvents	S_i	$S_v = \frac{X_e}{X_d}$	Viscosity (cP)
—	n-Hexane	0	0.01	0.31

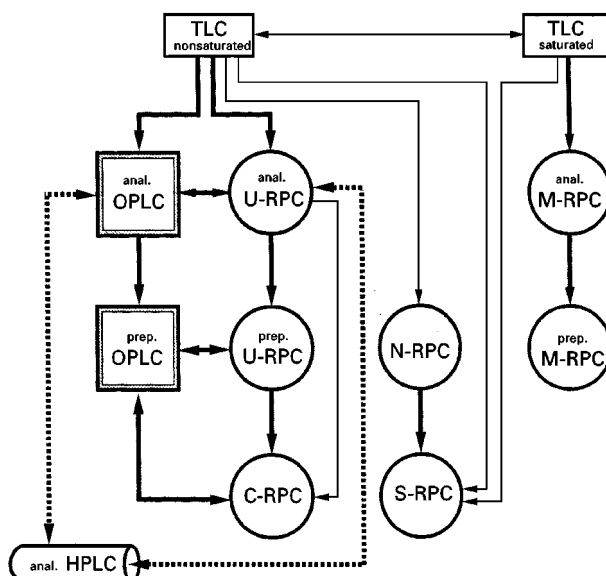

Figure 4 Mobile phase transfer possibilities between different planar chromatographic methods and HPLC, and fully online FFPC techniques.

The optimized TLC mobile phase can be transferred from unsaturated chromatographic tanks to analytical OPLC and U-RPC without modification of the selectivity. If the tank is saturated, the optimized mobile phase can be transferred to M-RPC. Transfer of the corresponding preparative methods (OPLC, U-RPC, M-RPC) from analytical normal-phase FFPC can be performed directly with the same mobile phase. Modification of the mobile phase used in the unsaturated TLC tank is necessary for transfer of preparative N-RPC or S-RPC separations. Direct mobile-phase transfer is also valid from OPLC and U-RPC to C-RPC. With the characterization of the different saturation grade of chromatographic chambers, excellent mobile phase transfer between analytical and preparative planar chromatographic methods and analytical HPLC can be achieved.

Vapour Phase

The selection of the vapour space is a variable offered only by planar chromatography. Three important factors have the greatest influence on this parameter – the chamber type, the ratio of the surface of chromatographic plate to the chamber volume, and the temperature.

Basically, one can distinguish between normal (N) and sandwich (S) chambers. In the conventional N-chamber there is a distance of more than 3 mm between the layer and the wall/lid of the chromatographic chamber. If this distance is smaller, the cham-

ber is said to have the S-configuration. Both types of chromatographic chamber can be used for unsaturated or saturated systems, and the chambers used for FFPPC separation can be also assigned to the earlier mentioned two categories.

Rectangular glass N-chambers are most frequently used for classical PPC (CPPC). Starting the separation with unsaturated chromatographic tanks generally gives higher R_F values for NP systems because of the evaporation of the solvents from the surface of the layer. Disadvantages of using unsaturated tanks are that it can result in a concave solvent front, leading to higher R_F values for solutes near the edges; the reproducibility of this effect and of the R_F values can be poor. If the layer is placed in the chamber immediately after introduction of the mobile phase, separation starts in an unsaturated system which will become progressively more saturated during the course of the separation (Figure 5A). A chamber is saturated when all components of the solvent are in equilibrium with the entire vapour space before and during the separation. A rectangular glass tank (N-chamber) with inner dimensions of 21 cm \times 21 cm \times 9 cm is most frequently used. These tanks can be used for development of two 20 cm \times 20 cm preparative plates with 50–100 mL mobile phase. The chamber must be lined on all four sides with thick filter paper (Figure 5B) thoroughly soaked with the mobile phase (by shaking) and must stand for 60–120 minutes to become saturated with the vapour phase. Each plate must lean against a side wall, so the plates do not touch each other. The advantages of saturated tanks are that the ' α ' front is much more regular and that the separation efficiency is higher for a development distance of 18 cm.

Of the different FFPPC techniques, normal chamber RPC (N-RPC), in which the layer rotates in a stationary N-chamber, belongs to this category. Because of extensive evaporation in the extremely large vapour space, this chamber is practically unsaturated.

S-chambers are very narrow unsaturated tanks, the plate with the layer is usually sandwiched with a glass cover plate (Figure 5C). Saturation can be established with a facing chromatographic plate that has been soaked with the mobile phase (Figure 5D). Part of the stationary phase of the plate to be developed is removed by scraping, so that initially the mobile phase can only reach the level of the facing plate. After sorptive and capillary saturation of this plate, the depth of the mobile phase is increased to start the separation. The U-chamber is a special variety of S-chamber in which the vapour space is reduced (Figure 5E). All basic development modes enable both equilibration before development and a choice of flow rates for separation.

Figure 5 Chamber types used for conventional PPC. (A) Unsaturated N-chamber (1, rectangular chamber; 2, chromatographic plate; 3, mobile phase). (B) Saturated N-chamber (4, filter paper soaked with the mobile phase). (C) Unsaturated S-chamber (5, glass cover plate; 6, spacer). (D) Saturated S-chamber (7, facing chromatographic plate, soaked with the mobile phase; 8, second part of the mobile phase). (E) Ultra-micro chamber, a special variety of S-chamber (5, glass cover plate; 9, elastic inert material).

The chambers used for preparative OPLC separations are unsaturated S-chambers, theoretically and practically devoid of any vapour space. This must be considered in the optimization of the solvent system. M- and U-chambers in RPC also belong to the S-chamber type. The difference between these two chambers is that the former is rapidly saturated, whereas in U-RPC the lid of the rotating chamber is placed directly on the chromatographic plate so that there is practically no vapour space and the chamber must be regarded as unsaturated.

The ratio of the surface area of the chromatographic plate to the chamber volume plays a role only if the separation is started in unsaturated tanks. The higher this ratio, the more unsaturated is the chromatographic chamber.

In saturated chromatography chambers the temperature does not exert a great influence on preparative separations. With unsaturated tanks the composition of the mobile phase plays a more pronounced role and it is important to note that temperature control is now important if separations are to be reproducible.

Figure 6 Calculation of the effect of chamber saturation on the separation.

For characterization of chamber saturation, a test-dye mixture can be developed with dichloromethane. If the hR_F values of the dye mixture are the same in different chambers on a given stationary phase, the extent of chamber saturation is identical. For comparison, the hR_F values obtained from different chambers can be depicted in a coordinate system. The hR_F values of any given system are plotted along the y axis and those from the system being compared along the x axis. If the chamber saturation is identical, a linear relationship is obtained, and $\text{tg } \alpha$ for the line is 1. If the hR_F values obtained in the second system were

smaller, the vapour phase was more saturated and $\text{tg } \alpha > 1$, or $\alpha > 45^\circ$. Conversely if $\text{tg } \alpha < 1$, or $\alpha < 45^\circ$, the vapour phase in the second system was less saturated. These possibilities are illustrated by results A and B in Figure 6. With this approach the chamber type can be characterized for a certain separation without specification of the vapour phase. The technique also provides guidelines for the transfer of mobile phases between the different planar chromatographic methods.

Development Mode

The ascending mode, in which the mobile phase moves up the plate, is most frequently used with a maximum separation distance of 18 cm. The angle at which the plate is supported during development affects the rate of development and the shape of the bands. As the angle of the plate decreases towards the horizontal development mode, the flow of the mobile phase increases, but so also does spot distortion. An angle of 75° is recommended as optimum for development. Because descending development has no significant advantages in terms of resolution, it is rarely used.

The advantages of circular development of compounds in the lower R_F range are well known, but it has not been accepted for preparative separations, because the mobile phase velocity would be too slow. However, it is possible to start development not directly from the centre, but from a circle of 2 cm radius, i.e. the mobile phase inlet is not a point, but a circle. Because the size of the mobile phase inlet and the velocity of the mobile phase are related linearly, a relatively high mobile phase velocity can be achieved over a separation distance of 8 cm. Recently a new device has been described which enables a suitable mobile phase velocity to be used in the circular development mode (Figure 7). A solvent reservoir

Figure 7 Schematic diagram of a circular preparative chromatography chamber. 1, glass plate; 2, chromatoplate; 3, support block; 4, magnet; 5, Teflon ring; 6, solvent reservoir; 7, quartz glass cover plate; 8, Teflon ring; 9, solvent.

made of steel and a silicone sealing ring are placed on the layer and fixed by a magnet located below the chromatographic plate. To start the separation, adsorbent is scratched from the centre of the plate and the recess produced filled with mobile phase. The device can be used for different types of chamber (N, UM). The entry of sample and mobile phase is regular over the whole cross-section of the preparative layer, irrespective of whether the sample is applied as a liquid or a solid. The device ensures rapid, efficient separation with all the advantages of circular development. The resolution is significantly higher than that obtained from linear development. With the UM chamber the glass cover plate is placed directly on the surface of the chromatographic plate. In the N chamber, the cover plate is placed on a 19 cm diameter metal ring, the height of which can be varied between 0.5 and 2 cm, depending on the type of chamber applied. To start development the solvent reservoir is filled with the appropriate mobile phase and the level of this is kept constant by applying a constant hydrostatic pressure by means of a second reservoir. To stop development the inlet from the second reservoir is turned off.

Anticircular development is accepted in analytical TLC for increasing resolution in the higher R_F range. Because a special device is necessary for such separations, this development mode is rarely used.

Although the different types of multiple development (MD) are rarely used for preparative purposes, the advantage of the method should be understood. In MD the first development length is the shortest and subsequent developments are performed over longer development distances. The last migration distance is the longest and corresponds to the useful development length of the chromatographic plate; it also depends on the nature of the mobile phase. The removal of the mobile phase between development steps is performed by careful drying of the plate. The dried layer is returned to the development chamber for repeated development under the same chromatographic conditions as for earlier development steps.

The most important aspect of MD techniques is the spot-reconcentration mechanism. In each development step the solvent front first contacts the lower part of the chromatographic zone formed in the previous chromatographic step. The molecules at this part of the zone start moving with the mobile phase toward the molecules in the upper part of the chromatographic zone – those still ahead of the solvent front. As the mobile phase front reaches the upper part of the zone, the narrow band developed as a result of the zone reconcentration mechanism migrates and broadens by diffusion in the mobile phase, as in conventional planar chromatography.

In terms of development distance and mobile phase composition, MD techniques can be classified into four basic categories – UMD, IMD, GMD, and BMD (Figure 8). Unidimensional multiple development (UMD) is the repeated development of the chromatographic layer over the same development distance (D) with the same mobile phase (same values of S_{T1} and S_{V1}). In the modification of UMD known as incremental multiple development (IMD) re-chromatography is performed over increasing development distances ($D_1 \rightarrow D_5$) with the same mobile phase (same values of S_{T1} and S_{V1}). In gradient multiple development (GMD), successive chromatographic development steps are performed with a change in solvent strength and selectivity ($S_{T1}, S_{V1}; S_{T4}, S_{V4}$) over the same development distance (D is constant). GMD is required for analysis of multicomponent mixtures spanning a wide polarity range. The most complex multiple development technique is bivariate multiple development (BMD), in which development distance and mobile phase composition are varying simultaneously ($D_1, S_{T1}, S_{V1}; D_4, S_{T4}, S_{V4}$) during successive chromatographic developments. Needless to say, the solvent strength and selectivity of the mobile phase can be changed independently of each other. For the analysis of less complex mixtures of wide polarity range, the preferred technique is BMD with a mobile phase gradient of decreasing solvent strength, when the final chromatographic separation can be detected as a single chromatogram. In BMD the shortest development is performed first with the mobile phase of strongest solvent strength; the chromatographic distance is increased and the solvent strength reduced during successive steps of the chromatography, until finally the last development step is performed over the longest development distance with the weakest mobile phase.

Separation Distance

The separation distance depends on the dimensions of the plate, the mode of development, the particle size, and the size distribution. The last property cannot be influenced by the user of pre-coated chromatoplates. Because in classical PPC capillary action is effective only for plates up to 20 cm in length, the maximum separation distance is 18 cm. For circular development the separation distance is 8–9 cm; in anticircular mode this distance is 8 cm maximum. Despite the short separation distance, correct selection of mobile phase and development mode can give high resolution.

The separation pathway in CPPC can be increased by use of a sequential technique in which the mobile phase supply to the plate is fully variable in time and

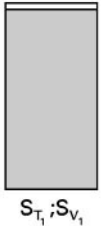

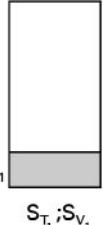

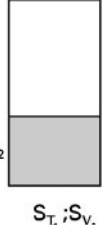

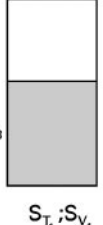

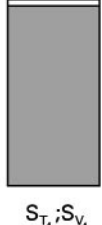

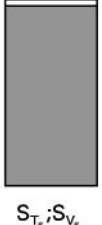

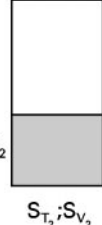

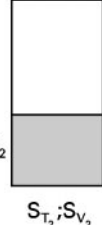

Method	Number of development				
	1	2	3	4	5
U M D					
					
					
					
					

Figure 8 Multiple development possibilities for PPC separations.

location. The principle of this technique is that the mobile phase velocity is much higher at the beginning of separation than later. After an initial separation, the layer is carefully dried, and the mobile phase applicator is placed between two separated zones, irrespective of whether the same or a different mobile phase is used. The supply of mobile phase can be stopped at any time to transfer it directly to the area of the compound zones to be separated. This always gives the highest initial velocity of the mobile phase, which substantially shortens the analysis time. The sequential technique for preparative separations can be performed with a special device—the Mobil- R_F chamber.

The separation pathway in S-RPC becomes theoretically unlimited as a result of a special combination of the circular and anticircular development modes. With this technique the mobile phase can be introduced onto the plate at any desired place and time. The solvent application system works in circular mode and with the aid of capillary action against the reduced centrifugal force (anticircular mode). Generally the circular mode is used for the separation and the anticircular mode for pushing the substance zones back to centre with a strong solvent. After drying the plate at a high rotation speed, the next development with another suitable mobile phase can be started. S-RPC is selected when the separation problem

cannot be solved with a single mobile phase, but optimized mobile phases are available for the separation of the individual compounds. Also the sequence technique can be employed for fast elution of previously separated compounds with a solvent of high strength.

Sample Application

Sample application is one of the most critical steps in PPC. The sample can be applied either offline or online. In offline mode the mobile phase comes into contact with the stationary phase only when sample application is complete; the separation is always started with a dry layer. This mode of application can be used for all PPC methods, irrespective of the driving force (capillary action or forced flow). In online application the sample is dissolved and the stationary phase is always wetted with a solvent – generally it is equilibrated with the starting composition of the mobile phase. This application mode is only possible when forced-flow techniques are used.

Offline Liquid-Phase Sample Application

The preferred method of placing a sample on a preparative layer is to apply it as a narrow streak across the plate. It is highly desirable to have the streak as straight and narrow as possible. With practice it is possible to streak a plate correctly by hand, using a syringe; the use of a Teflon tip on the end of the syringe has the advantage that no mechanical disturbance of the layer occurs. On applying a large amount of sample, the streak can be focused simultaneously and concentrated to a relatively thin line by the sequential technique, especially with nonpolar samples.

Application of a continuous streak can be automated. Most available applications can give a sample zone < 3–4 mm wide and up to 200 mm long for preparative separations. When the layer is not overloaded with sample it is generally accepted that the streak should be applied across the plate 2 cm from both edges. These areas are left free, partly because of the edge effect, which can cause migration of the mobile phase to be faster or slower at the edge than on the centre of the plate. For separations of extremely large amounts, the sample can be applied over the whole width of the plate. Otherwise migration of the mobile phase would be faster in the sample-free areas, resulting in poorer resolution.

When using pre-coated preparative plates with concentrating zones, the quality of streaking is not very important because the sample is applied to a practically inert zone. Pre-coated preparative layers with concentrating zone can be successfully used for PPC and for linear OPLC.

For preparative rotational planar chromatography (RPC), a concentrating zone can be self-prepared. The layer is removed by scraping to furnish a larger inner circle; a slurry with inert material is then cast in this circle. After final drying and scraping, the layer has a preadsorbent zone of approximately 2 cm. For C-RPC separations, after filling the planar column with the selected stationary phase, the last 1 cm can be filled with a deactivated sorbent.

Offline liquid-phase sample application can be used for practically all micropreparative and preparative PPC methods. The only exception is C-RPC, where the solvent for dissolution of the sample is not identical with the mobile phase. The planar column prevents elimination of the sample solvent. The separation may consequently be distorted, especially if the solvent has a higher solvent strength than the mobile phase.

Offline Solid-Phase Sample Application

Preparative solid-phase sample application is especially useful whenever a large amount of sample must be applied and/or the sample is soluble in nonvolatile solvent only. The sample must be dissolved in a suitable solvent and mixed with approximately 5–10 times its weight of deactivated sorbent. The sorbent with the adsorbed sample is dried and then introduced into a layer which has to be prepared to accept it. A 180 mm × 5 mm channel with a U-shaped profile can be scratched from the stationary phase. After removal of the sorbent from the channel, the prepared sorbent with the adsorbed sample is placed in the channel and pressure is applied to ensure optimum contact between the stationary phase of the chromatographic plate and the applied sample. Offline solid phase sample application is useful not only for conventional PPC but also for linear OPLC and C-RPC separations. In OPLC the prepared plate is placed horizontally in the OPLC chamber and the separation can be started with a relatively high inlet pressure. Because of the forced flow, any possible lack of suitable contact has no effect on the efficiency of the separation. With C-RPC the column must first be filled with stationary phase, then with the solid sample. Because of the centrifugal force no lack of suitable contact can occur.

Online Sample Application

In FFPPC the sample can also be applied to a wetted stationary phase, preferably to a plate equilibrated with mobile phase. This mode of application can be used not only for the various methods of preparative OPLC and RPC but also for semipreparative purposes. For plates without a concentrating zone and

online sample application, the separation time is increased because of the longer separation distance. When using the plates with concentrating zone, the effect of the reduced separation distance (2.5–4 cm) is compensated for by the efficiency of the concentrating zone. Because of these results, preparative separations with online sample application and plates with concentrating zones gave practically the same resolution in a shorter time than with the use of offline sample application on plates without concentrating zones. The mode of sample application has no significant influence on the resolution and is independent of the type of plate (analytical, preparative, with or without concentrating zone).

Location and Removal of Separated Compounds

After the preparative chromatographic plate has been developed and the mobile phase evaporated, the separated bands must be located and the desired compounds removed from the plate. If the compounds of interest are coloured, their position on the layer can be located under white light. If they are fluorescent, or become so after post-chromatographic derivatization, their position on the layer can be determined under UV light. Conversely, a PPC plate containing a fluorescent material will indicate the separated compounds as dark zones on a bright background when examined under UV light. Pre-coated plates containing 254 nm or 365 nm fluorescent indicators should be used if possible because they provide a mode of detection which is generally nondestructive.

If the compounds themselves are not visible or fluorescent, detection can be performed by use of iodine vapour or by use of destructive reagents (e.g. vanillin–sulfuric acid). If such a reagent is used for detection of the separated compounds, a vertical channel must be scraped in the layer about half a centimetre from the edge of the streak. After covering the major portion of the layer with a suitable glass plate, the part of the layer which is not covered is sprayed, and thus serves as a guide area. If heating is necessary for detection, the sprayed portion of the plate must be detached from the rest, by use of a glass cutter, because heating the developed preparative plates may lead to decomposition of the compounds of interest.

After location of the desired compound, the subsequent steps are: (1) mechanical removal of the adsorbent zone, (2) extraction of the compound from the stationary phase with a suitable solvent, (3) separation from the residual adsorbent, and (4) concentration of the solvent. The areas of the layer containing the compounds of interest are then scraped off cleanly down to the glass with a suitable scraper. One of the

best methods is to put the adsorbent with the compound to be extracted in an empty receptacle containing a sintered glass filter to retain the adsorbent and to extract the compound with a solvent and the aid of vacuum.

The substance should be highly soluble in the solvent or solvent mixtures used for extraction; the solvent should also be as polar as possible. Chloroform is widely used for nonpolar substances, and ethanol or acetone for polar compounds. If water is the chosen solvent, it should be removed by lyophilization. Because silica is significantly soluble in methanol, this solvent should be avoided. The mobile phase used for the separation is highly recommended also for extraction. As a rule of thumb the volume of solvent (V_{solvent}) required when the chromatographic mobile phase is chosen for extraction is as in equation [1]:

$$V_{\text{solvent}} = 10 \times (1.0 - R_F) \times V_{\text{scraped}} \quad [1]$$

It should be noted that the longer the substance is in contact with the adsorbent, the more likely decomposition is to occur. Once the solution of the compound to be isolated is obtained (free from adsorbent) the extract must be evaporated to dryness. The evaporation temperature should be as low as possible, to avoid decomposition.

Selection of Appropriate PPC Method

All types of PPC can be used for purification and isolation in the micropreparative and preparative range. As a rule of thumb, if the sample contains more than five substances, up to 10 mg of sample can be separated by a micropreparative method and up to 500 mg by a preparative method. If the sample contains fewer than five substances, these values can be increased to 50 and 1000 mg.

Conventional PPC can be used successfully, if: (1) no more than five compounds must be separated, (2) the compounds to be isolated are distributed over the whole R_F range and are present in more or less the same amounts, and (3) the total amount of sample does exceed 150 mg. This is the simplest and therefore the most widely used method.

Online OPLC can be used for the separation of five to seven compounds in amounts up to 300 mg. The use of centrifugal force for online purification and isolation is the oldest forced flow method. Generally, a 15 μm particle size stationary phase is used with all the advantages of the free selection of the size of the vapour space and the development mode. Up to ten compounds in amounts up to 500 mg can be isolated using the appropriate RPC method.

Table 2 Comparison of PPC methods at their present state of development

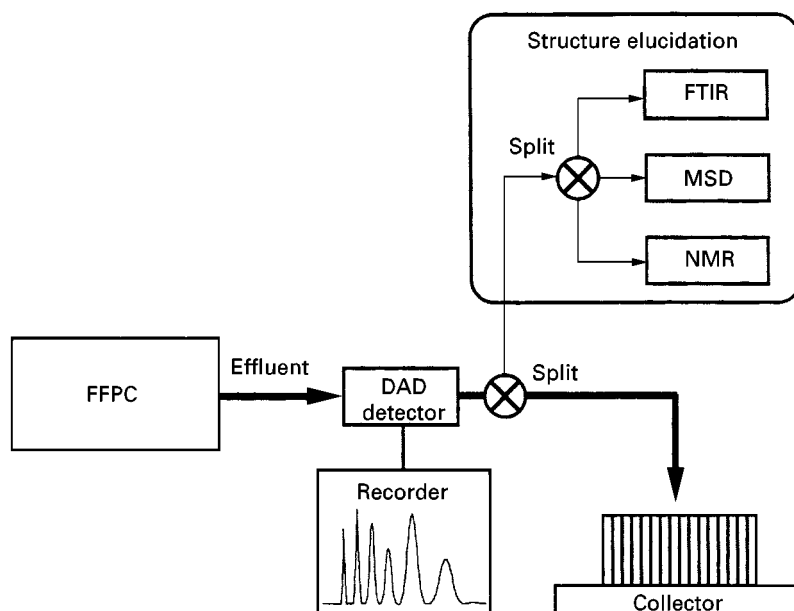

Viewpoint	CPPC	OPLC	RPC (N-, M-, U-, S-, C-RPC)
Migration of mobile phase	Capillary action	Pressure	Centrifugal force/capillary action
Layer/column	Pre-coated	Pre-coated	Self-prepared/filled
Stationary phase	Silica, RP-2, RP-18	Silica	All available
Particle size of stationary phase	$5\text{ }\mu\text{m} < x < 40\text{ }\mu\text{m}$	$5\text{ }\mu\text{m} < x < 40\text{ }\mu\text{m}$	$5\text{ }\mu\text{m} \leq x \leq 15\text{ }\mu\text{m}$
Layer thickness	0.5, 1, 2 mm	0.5, 1, 2 mm	1–4 mm
Volume of stationary phase	Constant	Constant	Increasing (constant)
Vapour space	Normal tank	None	Variable (N, M, UM, none)
Separation distance	18 cm	18 cm	12 cm (unlimited)
Separation mode	Linear (circular)	Linear (circular)	Circular (circular–anticircular)
Isolation	Offline	Online (offline)	Online
Typical amount of sample	50–150 mg	50–300 mg	50–500 mg
Number of compounds	2–5	2–7	2–12

Comparison and Outlook of PPC Methods

The principal differences between classical PPC, OPLC, and RPC are summarized in Table 2 which lists the generally accepted characteristics of the methods. As is apparent, the major difference between the methods is the nature of mobile phase migration. Better resolution can always be achieved by use of forced-flow techniques (OPLC, RPC) because the mobile phase velocity is nearer to the optimum; the use of online separation eliminates the need to scrape the separated compounds from the plate and means that all the compounds migrate over the whole separation distance. This enables connec-

tion of a flow detector, recorder, and fraction collector. These techniques require more sophisticated instrumentation. Unfortunately, the particle size and size distribution of pre-coated plates for OPLC are at present inadequate for this preparative technique.

Modern online forced flow methods enable not only micropreparative (OPLC) and preparative (RPC) separations, but – using appropriate split systems – also the hyphenation of these methods with different spectroscopic techniques like diode-array detection (DAD), FTIR, MS, and NMR, as is apparent from Figure 9. In this way not only isolation but also structure elucidation can be carried out in a single operation process.

**Figure 9** Combination of preparative FFPC and modern spectroscopic methods.

The greatest flexibility with regard to choice of stationary phase, particle size, layer thickness, and chamber type is provided by RPC. Because of the availability of suitable vapour phases and combination of development modes, RPC offers the greatest separating power both in terms of the amount of sample and number of compounds to be separated.

It can be stated that PPC covers a special range of preparative separations. PPC does not compete with column liquid chromatography for purification and isolation of compounds from a complex matrix. Instead, the two approaches are complementary and together they enable successful and rapid separation. It is expected that as a result of development of modern forced-flow and multiple-development techniques, PPC will further expand its importance in the isolation and purification of natural and synthetic products.

Radioactivity Detection

Introduction

Thin-layer chromatography (TLC) is a technique which has been applied to a wide range of chemicals since its introduction in the early 1950s. The only limitation to its use is that a suitable method of detection must be available; however, this limitation is removed when the compounds of interest are radiolabelled. Nevertheless, since the introduction of thin-layer radiochromatography (TLRC), one major drawback in gaining widespread acceptance has been the lack of an easy method to quantify the distribution of radioactivity whilst still maintaining good resolution. The available detection methods have either been very time-consuming (e.g. autoradiogra-

phy) or labour-intensive (e.g. zonal analysis) or could not match the resolution of the TLC separation itself. Over the years TLRC detectors have evolved and significantly improved, starting with scanners in the 1960s, followed by linear analysers in the 1980s and now the new 1990s generation of bioimaging analysers and InstantImager. The limitation of the scanners and linear analysers is that their resolution is lower than can be achieved by TLC itself. New detector technology such as phosphor imaging will lead to a renaissance in the use of TLRC due to the excellent resolution.

Detection and Measurement

The principal methods for detecting and quantifying radioactivity on TLC plates are autoradiography, zonal analysis (plate scraping followed by liquid scintillation counting) and direct measurement using radiation detectors. The method employed for

analysis depends on the available equipment, which generally depends on the amount of money available, and the type of experiment and information required. The various detection methods are discussed below and the technical descriptions in the present review provide information relating to the state-of-the-art modern-day detectors.

Autoradiography

Autoradiography is a detection method in which X-ray or photographic film is exposed to emissions from radioisotopes on TLC plates to produce an image on the film. After exposure (exposure time depends on the amount of radioactivity per zone), the film is developed to reveal the location of the areas of radioactivity as darkened spots or zones of varying optical density. The density is related to the amount of radioactivity in the spot/zone. Quantification can be done either by densitometry using a calibration curve produced by exposure to radioactive standards or by removing the areas of radioactivity (scraping/cutting) and counting them by liquid scintillation. The three principal exposure methods are direct exposure (autoradiography), direct exposure with an intensifying screen and fluorographic exposure (fluorography). The approximate minimum amounts of radioactivity that are required to give a suitable image with a 24 h exposure are shown in Table 1 for the three different exposure methods.

Detection by direct exposure autoradiography involves intimate contact of the TLC plate with a photographic or X-ray film. Direct exposure is useful for all of the β -emitters, with the possible exception of low-level tritium-labelled samples. To improve the detection efficiency for γ -emitting e.g. ^{125}I and high energy β -emitting isotopes (e.g. ^{32}P), the plates are exposed with intensifying screens placed behind the film. Commercially available intensifying screens consist of plates coated with inorganic phosphors. The fraction of radiation that passes completely through the film is absorbed by the phosphor,

which in turn emits light that produces additional exposure of the film. The enhancement in sensitivity using an intensifying screen with preexposed film (see preflashing below) is of the order of 7–10-fold for ^{32}P and 16-fold for ^{125}I when compared to direct exposure without the screen.

Weak β -emitting isotopes (e.g. ^3H), adsorbed on TLC adsorbents, are inefficiently detected by direct exposure to X-ray films. The principal reasons for this inefficiency are the low energy and short range of the β -emissions and the barrier imposed by the protective coating of the X-ray film. To increase the sensitivity for these isotopes, a technique termed fluorography is employed. Fluorography involves the overcoating or impregnation of a scintillator into the TLC plate followed by direct exposure of the treated plate to the X-ray film. The scintillant, being in direct contact with the isotope, emits light when activated by the β -emission and exposes the film photographically. For efficient detection, the spectral sensitivity of the film should be matched to the wavelengths of light emitted by the scintillator. The scintillants can be incorporated by mixing with the adsorbent during preparation of the TLC plate or applied after development. Fluorographic reagents, such as 2,5-diphenyloxazole (PPO), can be added by spraying or dipping the plates.

The sensitivity of the technique can be further improved by lowering the exposure temperature and pretreating the film by partially exposing the film to a controlled flash of light (preflashing) before exposure to the radioactive sample. Preexposure to a flash of light greatly increases sensitivity and corrects the nonlinear response at low exposure levels. For maximum enhancement in sensitivity, both preflashing and cooling to temperatures between -70 and -80°C are utilized.

Zonal Analysis

The basic procedure involves removing areas of chromatographic adsorbent from a TLC plate

Table 1 Approximate lower detection limits on TLC plates for various exposure methods (dpm cm^{-2} with a 24-h exposure)

Exposure method	^3H	^{14}C	^{32}P	^{125}I
Direct exposure (autoradiography)	$2.6\text{--}13 \times 10^5$ ^a	$220\text{--}650$ ^a	500 ^d	1600 ^d
Direct exposure with intensifying screen			50 ^{d,e}	100 ^{d,e}
Fluorographic exposure (fluorography)	$2.0\text{--}6.6 \times 10^3$ ^{b,c}	$50\text{--}450$ ^{b,c}		

^a Average range for direct exposure of film at temperatures between -78.5 and 25°C .

^b Treated with a 7% solution of 2,5-diphenyloxazole (PPO) in diethyl ether and exposed at a temperature of -78°C .

^c Treated with a mixture of 0.5% 2,5-diphenyloxazole (PPO) in methyl anthranilate at -80°C with Kodak X-OMAT AR film.

^d Exposed at a temperature of -78°C .

^e Preexposed Kodak X-OMAT R film with a calcium tungstate X-ray intensifying film. (Reproduced with permission from Clark and Klein, 1996.)

followed by measuring the associated radioactivity with each spot or zone. The zones are removed either by scraping the adsorbent from the plate (plate scraping) or by cutting pieces from flexible-backed plates and transferring the segments into counting vials. In an alternative procedure, which allows isolation of the radiolabelled sample, the plates are segmented and the radioactive components are eluted from the adsorbent with solvents and counted. To ensure maximum recovery of radioactivity by elution with solvent, the adsorbent should first be crushed to a fine powder. Measurement of radioactivity is generally accomplished using a liquid scintillation counter for the weak β -emitters. For the γ -emitters, the sectioned zones are counted without further sample preparation in an appropriate γ -counter.

This technique is relatively sensitive and provides quantitative detection for samples containing low levels of radioactivity. Single peaks containing 100 d.p.m. can be readily detected. Zonal analysis has been reported to be both as sensitive and specific as gas chromatographic-mass spectrometric analysis in the assay of [^{14}C]-labelled clinical samples. When the radiochromatograms are cut into sections and quantified using a γ -counter for the analysis of γ -emitting isotopes, the method is as precise as TLC scanning.

Radiation Detectors

Over the last 30 years or so the detection of radioactivity on TLC plates has taken dramatic leaps forward. Prior to the introduction of radiation detectors, the classical method used for the detection and quantification of radioactivity on a plate involved firstly exposure to X-ray film. This could take from a few hours up to 1–2 months and this technique only located the radioactivity. The second step after location was quantification which was achieved by removing the zone of interest, either by scraping off the silica gel or by cutting away if the plates were aluminium or plastic, followed by liquid scintillation counting. Such a procedure is extremely labour-intensive and is limited in terms of accuracy and resolution (see above).

The first radiation detectors were called radioscaners and these were developed and introduced in the early 1960s. This was a major step forward in the automatic detection and subsequent quantification of radioactive components on TLC plates. The sensitivity and resolution of the instruments were not very high but peaks could be detected and their relative amounts subsequently quantified. At around the same time, spark chambers were also developed for use with TLC plates. Although, these detectors could locate individual components on TLC plates, quantification was not possible.

Another major step forward for radio-TLC came in the early 1980s when the so-called linear analyser was introduced. This instrument was easier to use and more sensitive than the old scanners and was automated to the extent that up to four plates could be run overnight. As a consequence, improved quantitative results were obtained and analysis time was shortened. However, resolution was still not as good as that obtained by using autoradiography and two-dimensional plates could not easily be evaluated.

Currently there are a number of instruments available which have equal resolution to that obtained with autoradiography or are at least approaching it. These instruments include those using the new phosphor imaging technology, the multi-wire system, or the multi-detector system (micro-channel array detector).

The basic functioning of all these detectors is outlined below and a comparison of the advantages and disadvantages of each detector is given later.

Spark chambers The spark chamber is an easy-to-use, low cost technique for photographically locating areas of radioactivity on TLC plates. Exposure times are relatively short and the images obtained on Polaroid film can be quickly transferred back to the original chromatogram using an inbuilt episcopes print projector. This means that the areas of radioactivity can then be removed for efficient counting using a liquid scintillation counter. The spark chamber can also be used for the rapid qualitative screening of plant and tissue sections to assess the degree of uptake.

Reviews of spark chambers and their uses have been published previously. Essentially, the spark chamber consists of electrodes contained in a chamber filled with a mixture of argon containing 10% methane, and this gives a high sensitivity to β -radiation. The gas is ionized by radioactive emissions and these emissions are recorded on film with a camera. The Polaroid film integrates the individual flashes produced over a suitable exposure period. Due to the intensity of the sparks the film is rapidly saturated, leading to blackening of the film, and hence direct quantification is not possible.

Radioscanners These instruments were developed and first sold commercially in the early 1960s and utilize a mechanically driven windowless gas-flow Geiger counter. These counters have an interchangeable aperture plate (collimator slit) which controls the size of the area being measured. The TLC plate is scanned by the moving detector head and the signal obtained from the radioactivity source is amplified and recorded. The resultant chromatogram can then

be printed on a suitable recorder or integrator-plotter. When the speed of the scanner and recorder are synchronized the exact location of the radioactivity on the TLC plate can be obtained by aligning the chromatogram with the TLC plate. Some manufacturers continue to produce radioscanners but, due to the increasing number of new detection systems (described below) which have better sensitivity and resolution, the number of radioscanners available for quantitative TLC has decreased.

Linear analysers The introduction of the linear analyser provided a great boost for the users of radio-TLC since these detectors brought with them not only improved sensitivity and resolution but also much-improved automation. For example, up to four plates, each with several tracks, can be measured overnight and the chromatograms and accompanying quantitative tables automatically printed out. For the first time in this field the resultant data can be stored and reprocessed at a later date. With the development of new desktop publishing software, the chromatograms and quantitative results can be directly transferred into reports or publications.

The linear analysers currently used are based on imaging counters developed for high energy physics and medical imaging in the late 1960s and early 1970s. Essentially, the detector head moves automatically to any track on the TLC plate. Once in position the head is gently lowered on to the surface of this track of the TLC plate and the instrument is then ready to begin measurement. At this point the detector has formed a counting chamber since the TLC plate itself has closed the opening of the detector, making the counting chamber gastight. Immediately the detector is resting on the plate the flow of counting gas (argon/methane) is automatically activated and within a few seconds the counting chamber is purged of air and filled with the counting gas.

There are two kinds of systems available today which function in a similar way: each utilizes a different design to locate the exact position of the radioactivity on the plate. One system uses the resistive anode technique and a schematic diagram of this detector is shown in Figure 1. High voltage is applied to a 25 cm anode wire fixed along the length of a windowless detector (1 cm wide) and positioned directly above the TLC plate. This wire is constructed of carbon-coated quartz and has a high electrical resistance. When a radioactive emission enters the detector, the gas is ionized and electrons are produced along the particle track. The free electrons are accelerated towards the anode wire by the electric field produced by the high voltage. The electrons continue to ionize more gas as they approach the wire, and the

Figure 1 Schematic diagram of a linear analyser detector with a resistive anode wire. (Reproduced with permission from Clark and Klein, 1996.)

resulting number of electrons becomes large enough to be detected electronically. The pulse of electrons is collected on the anode wire near the position of the initial ionization. The charge divides in the wire, and pulses appear in the amplifiers located at both ends of the wire. The amplitude of the pulse measured by each amplifier is proportional to the resistance between that end of the wire and the position where the electrons were collected. The ratio of these two pulses is linearly related to the original position of the event on the wire. The position of each event is calculated and stored in a computer memory to provide a digital image of the distribution of radioactivity on the plate.

The second type of detection system uses the delay wire technique; a schematic diagram of this detector is shown in Figure 2.

The β -radiation (fast electrons) emitted from the radioactive source on the plate ionizes the counting gas which has been specifically chosen so that this process can freely take place. This is the primary mode of ionization and the resultant charged particles, free electrons and positive ions, are then accelerated towards the anode wire and cathode, respectively. In this primary mode of ionization the free electrons are accelerated to such an extent that they themselves cause ionization of the counting gas, producing further free electrons and ions and this is the secondary ionization mode. This continues, causing an avalanche of ions from the primary point of ionization towards the anode wire.

Concurrently, the positive ions produced move relatively slowly towards the cathode. These positive

Figure 2 Schematic diagram of a linear analyser detector utilizing a delay wire technique. TA, Time-to-amplitude; ADC, analog-to-digital converter. (Reproduced with permission from Clark and Klein, 1996.)

ions sometimes combine with electrons, producing ultraviolet radiation of sufficient energy to cause further ionizations in a process known as the photoelectric effect. Once sufficient ionization has taken place, a spark is produced, which gives rise to a pulse in both the anode and cathode. The amplitude of the pulse is proportional to the number of ions produced and hence this type of detector is generally called a proportional counter.

The above is a description of the principle of detection. The location of the source of the ionizations is obtained by making use of a delay wire. The delay wire is a very thin wire which is wound over the cathode and pulses pass along this wire in both directions. The pulses are detected by amplifiers at each end of the wire. The arrival of a pulse at one end starts the time-to-amplitude (TA) circuit, while the other pulse is delayed and provides a stop signal in the circuit. The difference between the time of arrival at the two ends of the wire can thus be measured and is proportional to the position of the initial ionization. An analog-to-digital converter (ADC) converts the TA signal to a digital position value that is processed by the data system.

Using this method of detection, the whole of the delay line remains active and thereby the entire length of the chromatogram can be measured at the same time. Once one track of a TLC plate has been measured according to the pre-set time, it automatically moves to the next and the measuring process is repeated.

Radioanalytic imaging system (Ambis) When this instrument was introduced in about 1988, a description of its functioning was reported. The Ambis 4000 directly detects β -particles from a wide variety of isotopes and is suitable for gels, blots, TLC plates and any sample type of the dimensions 20×20 cm. It is

reported in the company literature that this instrument can be 100 times faster than X-ray film.

The detector consists of 3696 individual detector elements (each giving a data point) configured in a hexagonal array. Image quality is improved by increasing the number of data points and this is achieved by moving the sample through 72, 144 or 288 discrete positions. Therefore, counts are recorded in 266 112, 532 224 or 1 064 448 data points (i.e. $3696 \times$ number of discrete positions) from which an image is obtained. This image can then be displayed on a monitor and the areas of radioactivity quantified. A background detector which operates concurrently and in a similar way is located above the main detector, and compensates for background radiation.

Different resolution plates, which have different size and shape apertures, can be inserted into the instrument and these plates control the resolution and efficiency (i.e. sensitivity) of the instrument. In general, this means that, using the correct aperture, the detector can be tuned to obtain maximum resolution (at the expense of sensitivity). Conversely, when the instrument is tuned for maximum sensitivity, this is at the expense of resolution. Therefore, aperture choice is governed by sample size and the number and resolution of components required within the sample.

Multiwire Proportional Counters (MWPC)

Digital Autoradiograph (Berthold) This two-dimensional detector is reported to be 100 times more sensitive than the linear analyser and measures all areas of radiation from a 20×20 cm surface simultaneously.

The radio-TLC plate is placed on the measuring table and is then automatically loaded into the detector, which also controls the flow of the P-10 counting gas (90% argon + 10% methane). The detector is principally a two-dimensional position-sensitive MWPC. Essentially, it consists of three parallel wire planes, X, Y and Z, each with 100 wires. The spacing between the planes and the wires is only a few millimetres. The central plane (Z) is maintained at a positive potential of 1800 V and the counting chamber is filled with P-10 gas. Charged pulses are generated on the Z plane wires by ionizing particles (β -particles). The orthogonally crossed wire planes X and Y, below and above Z, pick up the charge signals from the Z plane at their position of origin, hence the position of the radioactivity on the TLC plate can be located.

The signals from the wire planes are transmitted via preamplifiers, pulse shapers, discriminators and logic circuits to ADC which are finally coupled to a data acquisition system.

InstantImager (Canberra Packard) This microchannel array detector provides direct electronic detection and real-time imaging of radioactivity on flat surfaces such as gels, blots, tissue slices and, of course, TLC plates. The detector consists of an array of 210 420 so-called microchannels (diameter 400 μm) in a 20 \times 24 cm multilayer plate. The microchannel array plate is a laminated surface about 3 mm thick with alternating conductive and nonconductive materials. A voltage step gradient is applied to the successive conductive layers to create a high electric field (approximately 600 volts mm^{-1}) in the microchannels. The β -particle emitted from the radioactive source ionizes a gas (argon with small amounts of carbon dioxide and iso-butane) in one of the microchannels. The electrons produced are accelerated by the high electric field in the microchannel, further ionizing the gas, resulting in a cloud of electrons. In this way the microchannels serve as both collimators and preamplifiers.

The cloud of electrons migrates up an electric field gradient into a multiwire chamber located on top of the multilayer. This chamber consists of an anode plane of thin anode wires and two cathode planes (X and Y), as described above for the Digital Autoradiograph. Further avalanche amplification occurs, resulting in electric pulses in the X and Y cathode tracks. The resultant signals are digitized and then decoded to identify the microchannel in which the primary ionization took place, hence locating the position of the radioactive emission. A schematic representation of the microchannel detector is shown in Figure 3.

BioImaging/phosphor imaging analysers The phosphor imagers make use of an imaging plate which is a two-dimensional sensor formed by a layer of fine crystals of photostimulable phosphor (BaFBr : Eu^{2+}). The emitted β -energy is stored upon exposure. In the reading unit the imaging plate is scanned with a laser beam. The energy of the laser stimulates the stored

electrons to return to the ground state and to emit luminescence in proportion to the recorded radiation intensity. This luminescence is collected in a photomultiplier tube and converted into an electrical signal. A schematic diagram of the principle of detection is shown in Figure 4.

Data recording and analysis are carried out at a workstation. After reading, the image data on the imaging plate can be erased by exposure to incandescent light and thus the plate can be reused. Imaging plates for the normal weak β -emitters are available and a specially designed plate for tritium is available. An illustration of the whole imaging process is given in Figure 5.

A prerequisite for good results is to expose the plates in a lead shielding box, particularly those that require longer than 1–2 h exposure time. In this way the contribution of natural background radiation is reduced.

Over the last few years there has been a significant expansion in the variety of instruments available and in the type of imaging plates on offer. Instrumentation has been improved and targeted as far as applications are concerned. For instance, Fuji now has six Phosphor Imaging plate scanners (BAS 1000, 1500, 2000, 2500, 5000 and the new 1800) and Canberra Packard has brought out the Cyclone. Fuji also now offers the FLA 2000 which combines fluorescent and radioisotope detection. The major improvement in the BAS range of instruments has been in resolution, whereby the BAS 5000 can now operate with a resolution of 25 μm , although when used at this high resolution the storage memory required for each scan is extremely high.

Figure 5 Illustration of the phosphoimaging process. IP, Imaging plate. (Courtesy of Fuji Photo Film Co. Ltd, Tokyo, Japan.)

A further instrument using similar technology, recently introduced by Packard, is the Cyclone™. In this instrument, a solid-state diode laser and confocal optical system moves down the storage phosphor screen as the screen rotates on a carousel. In this process the laser excitation and light collection optics remain in a fixed position relative to the screen surface, so that laser bleed associated with other detectors is eliminated. Furthermore, light collection is increased compared to that obtained with fiberoptic bundles.

A range of imaging plates is now available and these should be chosen according to instrument and requirement. Currently, Fuji is the leading supplier and offers the BAS III, MP, SR, TR and ND imaging plates: care must be taken when selecting a plate because not all plates can be used with all instruments. A range of cassette sizes is also available from Fuji according to plate size.

Comparison of TLRC Detection Methods

As described at the beginning of this article, there are three principal techniques for the analysis of radio-

active components on TLC plates, autoradiography, zonal analysis and mechanical detectors (e.g. linear analysers, phosphor imagers, MWPC detectors). The technique of choice depends on a number of parameters but of primary consideration are sensitivity and resolution. Other parameters to be considered are quantification, linear dynamic range, speed, sample throughput and preservation of sample. A comparative summary of the detection methods with respect to these parameters is shown in Table 2.

Both autoradiography and zonal analysis have a number of drawbacks, including sensitivity and resolution, but primarily both techniques are extremely time-consuming. Linear analysers offer a good compromise between speed, resolution and quantitative accuracy. However, the performance of the linear analysers falls well below that of the currently available MWPC detectors and phosphor imagers in all respects. Sensitivity, quantification and, particularly, resolution are significantly superior, resulting generally in much better quality chromatograms. The phosphor imagers have slightly better resolution than the MWPC detectors but the disadvantage of phosphor imagers is that the chromato-

Table 2 Comparison of thin-layer radiochromatographic analysis techniques

Parameters	Autoradiography	Zonal analysis	Linear analyser	MWPC detector	Phosphor imager
Sensitivity	+	+++++	++	+++++	+++++
Resolution	+++++	+	++	++++	+++++
Quantification	+	+++++	+++++	+++++	+++++
Dynamic range	+++	+++	+++	+++++	+++++
Speed	+	++	+++++	+++++	++++
Sample throughput	+	+	+++	++++	+++++
Preserves sample	Yes	No	Yes	Yes	Yes

+++++, Excellent; +++++, very good; +++, good; ++, satisfactory; +, poor. (Reproduced with permission from Clark and Klein, 1996.)

gram development cannot be seen in real time. Also, for a single plate the analysis time with the MWPC detectors is quicker but when more sample throughput is required, then the phosphor imagers have the advantage since many plates can be exposed simultaneously.

In general, as the newer range of detectors were brought on to the market they were very expensive in comparison to the linear analysers. However, with increasing competition and technological developments, prices are slowly coming down.

Future Developments in TLRC

The new range of detectors have significantly improved sensitivity and resolution; most have a resolution of under 1 mm and the phosphor imagers are able to obtain a resolution of as low as 0.025 mm. Also, current detectors are now able to detect spots of radioactivity on a plate containing less than 10 d.p.m. in a relatively short period of time. As sensitivity and resolution are continually improving, the future major development of TLRC probably lies in the realm of full automation using robots, from the application of multiple samples to the TLC plate, to development and drying, transport to the detector, measurement and finally printing of the chromatogram and quantitative results.

Introduction

The detection of chromatographic zones on a developed thin-layer plate usually relies on the absorption or emission of electromagnetic radiation in the visible or ultraviolet range. Some compounds are visibly coloured, others absorb UV light or exhibit fluorescence when excited by UV or visible light, but most require visualization using an appropriate spraying or dipping reagent. Due to the inert nature of the adsorbents commonly used in thin-layer chromatography (TLC) layers, chemical reactions can be carried out *in situ* without destroying the adsorbent or binder characteristics. Many such detection reagents exist for TLC, and lists of formulations have been collated in a number of publications. Like a number of other features of the TLC procedure, this highlights the versatility and uniqueness of thin-layer chromatography compared with other chromatographic techniques. Often, quite aggressive reagents such as hydrochloric acid or sulfuric acid can be used to detect separated analytes *in situ*. Such reagents are included along with iodine vapour or nitric acid vapour as universal reagents that can be used to visualize a wide range of compounds of different types. Some of these can be termed destructive reagents, particularly those involving charring. Some reagents are much more specific for groups of compounds such as alcohols, aldehydes, ketones, esters or acids. These are termed group-specific reagents. With regard to specificity, this is about the limit of what is possible as no genuine substance-specific reagents exist. When no irreversible chemical reaction is used for detection on the chromatographic layer, the form of visualization is termed non-destructive. Included in non-destructive techniques are visible and UV light, and sometimes the use of iodine or ammonia vapour. The latter two reagents are included as in many cases the 'reaction' is reversible.

Often, separated compounds can be detected and visualized by a combination of the above techniques. A non-destructive technique may be used initially, followed by a universal reagent, and then finally a group-specific reagent to enhance selectivity and sensitivity. Often, for a particular analyte there may be several visualization reagents available, but usually there is a noticeable difference in sensitivity of detection between them. Also stability may play an

important part in the selection of a suitable detection reagent. Some reagents have good stability over a number of weeks, however, there are those that must be made up fresh and used almost immediately. The visualized chromatographic zones may also differ in stability. Some may fade quite quickly, whilst others, although remaining stable, become more difficult to visualize as the background darkens or is affected in some other way by the reagent. Fortunately, the majority of reagents do give acceptably stable results. Sometimes dark or coloured backgrounds can be lightened by exposure of the chromatographic layer to acidic or alkaline vapours. However, all these effects will need to be taken into consideration so that the most effective visualization procedure is used.

After visualization, further analysis can be performed by *in situ* spectrodensitometric scanning in the absorbance, fluorescence quenching, or fluorescence modes, in addition to removing some or all of the separated chromatographic zone for further analysis by infrared (IR), Raman, nuclear magnetic resonance (NMR), mass spectrometry (MS) or radiography. Using these hyphenated techniques, more useful analytical data can be obtained. In fact, the stability of the layers and the detected chromophores often allow useful data to be collected even if the TLC plate had been developed some days or weeks previously.

Non-destructive Methods

Visible Spectrum

Some compounds are sufficiently coloured, for example natural and synthetic dyes, and nitrophenols, to give an absorption in the visible part of the electromagnetic spectrum. However, it is the remaining part of the visible radiation that is reflected and is seen by either the naked eye or light-detecting equipment. Prechromatographic derivatization can often be used to improve resolution of the analytes of interest, but also make them visible to the naked eye. One example of this is the formation of yellow dinitrophenylhydrazones of ascorbic acid and its homologues.

Ultraviolet Spectrum

Colourless separated components on the TLC/high performance (HP) TLC layer may absorb electromagnetic radiation at shorter wavelengths than the visible spectrum. These are detected in the UV range, normally at 400–200 nm. Such compounds are detected using

UV-sensitive detectors, e.g. photomultipliers. Often exposure to UV light at short-wave radiation (254 nm) or long-wave radiation (366 nm) is all that is necessary for absorbing or fluorescing substances to be observed. Most manufacturers' UV lamps and cabinets function at either or both of these wavelengths.

To aid absorbance, many commercial pre-coated TLC layers contain an inorganic phosphorescent indicator or an organic fluorescent indicator. Inorganic indicators used include uranyl acetate (yellow-green), manganese zinc silicate, zinc cadmium sulfide, zinc silicate (green) and tin strontium phosphate (blue). Nearly all silica gel pre-coated plates and sheets contain this type of indicator. Most indicators exhibit a bright green, yellow or blue phosphorescence when excited by UV light at 254 or 366 nm.

Detection by absorbance in these cases relies on the phosphorescence being quenched by the sample components. This process is known as fluorescence quenching because the phosphorescence is very short lived. Hence, the effect is best observed by continual exposure to UV light. In most cases, pink or violet spots/bands are observed for quenching on the green phosphorescent background, whereas grey-black spots/bands are usually seen on the blue background. In most applications, the inorganic indicators are quite stable with little or no elution from developing solvents, and remain unaffected by most dyeing reagents and the temperatures used to effect reactions.

Organic fluorescent indicators can also be used. Most of these fluoresce in long-wavelength UV light (366 nm) and are coded F₃₆₆ or UV₃₆₆ by the manufacturer. Most cellulose pre-coated layers contain this type of indicator. Substances used include optical brighteners, hydroxypyrene sulfonates, fluorescein and rhodamine dyes. Some pre-coated plates are manufactured with both types of indicator present to give possible quenching by sample components at both wavelengths.

The process of fluorescence quenching is caused by the electromagnetic radiation providing the energy to bring about an electronic transition from the ground state to an excited singlet state. As the excited electrons return to the ground state, they emit the energy at a longer wavelength, usually in the visible range. Phosphorescence quenching is slightly different. Rather than returning directly to the ground state, the electrons enter an excited triplet state and then return from there to the ground state. As before, the energy is emitted at a longer wavelength. However, as the decay is longer the process is better described as phosphorescence rather than fluorescence.

Many analytes, however, either absorb insufficiently or not at all by these techniques. In these instances suitable detection reagents are used to give coloured

spots/bands *in situ*. If these are reversible reactions, then they can still be termed non-destructive techniques.

Reversible Reactions

Iodine Vapour

Iodine is a very useful universal reagent, but it should never be overlooked that some reactions with iodine are non-reversible (discussed later in Non-reversible Reactions). The use of iodine as vapour enables the detection of separated substances rapidly and economically before final characterization with a group-specific reagent. Where lipophilic zones are present on a silica gel layer, the iodine molecules will concentrate in the substance zones giving brown chromatographic zones on a yellow background.

Preparation of the reagent simply involves putting a few iodine crystals in a dry chromatography chamber, replacing the lid and allowing the iodine vapour to fill the tank for a few hours. The developed chromatogram is then introduced into the chamber and as soon as the chromatographic zones are recognized, the layer is removed and the results documented. The adsorbed iodine can then be allowed to evaporate from the surface of the layer in a fume cupboard. The chromatogram can then be subjected to further reactions. If more permanent results of the iodine impregnation are required, then the chromatographic zones can be sprayed or dipped in a starch solution (0.5–1%) to give blue starch-iodine inclusion compounds.

Iodine detection works well on silica gel 60 and aluminium oxide layers. However, results are usually poor on reversed-phase layers as the lipophilicity of the layer does not differ appreciably from the substance zones.

Iodine vapour reversible reactions occur with a wide range of organic lipophilic molecules, e.g. hydrocarbons, fats, waxes, some fatty acids and esters, steroids, antioxidants, detergents, emulsifiers, antibiotics and many miscellaneous pharmaceuticals.

Ammonia Vapour

Ammonia vapour is often employed in improving the sensitivity of visualization of organic acids where pH indicators like bromocresol green or bromophenol blue have been used initially. The presence of ammonia has the effect of giving a sharper contrast between the chromatographic zones and the plate background. The process of exposure to ammonia vapour can be carried out simply by holding the chromatographic plate face down over a beaker of strong ammonia solution. However, it can be done more

elegantly by pouring ammonia solution into one compartment of a twin trough developing tank and placing the TLC plate in the dry compartment. With the lid in place the TLC plate is exposed to an almost even concentration of vapour. The process is reversible with time as the ammonia soon evaporates from the adsorbent surface.

Non-reversible Reactions

Destructive Techniques

Most post-chromatographic chemical reactions on the layer could be described as 'destructive' in that a chemical reaction has taken place and visualized compounds are no longer those that were applied as the sample. However, in order that a clear distinction can be seen between a truly destructive technique and a chemical derivatization or other chemical reaction, the destructive techniques described here will be limited to charring and thermal activation.

Charring techniques Charring usually involves treatment of the developed chromatogram with sulfuric acid and then heating at temperatures of 100–180°C for 5–20 min. The reaction is fairly non-specific, detecting most substances that are organic in nature as carbon deposits. Hence, sulfuric acid can also be termed a 'universal reagent'. Sometimes fluorescent chromatographic zones are produced at temperatures below 120°C, but their intensities are very dependent on the time of heating. Most charring occurs at higher temperatures, typically 150–180°C.

Although sulfuric acid charring is a relatively easy technique, there are limitations. Overheating of manufactured pre-coated layers results in the whole layer turning grey or even black. The problem is that commercial binders in pre-coated layers will also char under extreme heat in the presence of sulfuric acid. Most sulfuric acid reagents for dipping and spraying commercial TLC plates consist of a 10–20% v/v solution in water/methanol. Charring reactions will also occur sometimes with other acids, e.g. phosphoric acid. In conjunction with copper acetate, lipids can be detected by charring at 180°C.

A further point to bear in mind is the care that needs to be taken if charring techniques are used in conjunction with reversed-phase silica gel layers. Due to the carbon loading, excessive heating will cause a dark or even black background to appear.

Thermal activation techniques It has been observed that heating some substances to high temperatures on certain chromatographic adsorbents results in

chromatographic zones that are fluorescent under exposure to UV light. This process is known as thermochemical activation. The moderately polar stationary phase, a NH₂-bonded silica gel layer, gives the best results for this type of detection.

It has been postulated that under the catalytic influence of the surface of the silica gel bonded layer, functional groups are eliminated and aromatic ring systems develop, which are excited by long wavelength UV light at 366 nm. In general, compounds with heteroatoms (nitrogen, oxygen, sulfur and phosphorus) more readily undergo this reaction than pure hydrocarbons. Under the influence of the catalytic adsorbent surface, substances rich in π -electrons are formed that conjugate to produce products that are fluorescent when appropriately excited. Changes in pH can alter the excitation and fluorescing wavelengths.

The derivatives formed remain stable for weeks, and the fluorescence can frequently be intensified and stabilized by dipping the chromatogram in organic solvent solutions of Triton X100, liquid paraffin and polyethylene glycol. If the NH₂-bonded layer contains a fluorescent indicator (F₂₅₄), then often appreciable fluorescence quenching can occur under UV light at 254 nm. Sometimes compounds that only weakly fluoresce can exhibit strong fluorescent absorption (e.g. vanillic acid and homovanillic acid). Thermal activation works well for the detection of catecholamines, fruit acids and some carbohydrates.

Chemical Reactions on the Layer

Most chemical reactions on the planar chromatographic layer are carried out after development of the chromatogram. This is described as post-chromatographic visualization and is particularly useful when the presence of 'unknowns' in the sample need to be detected. However, it is also possible, as will be shown later, to carry out a pre-chromatographic derivatization before chromatographic development and this can have significant advantages. As post-chromatographic visualization is the major method of detection, it is this technique that will be given consideration first.

Post-chromatographic visualization Post-chromatographic identification of chromatographic zones can be achieved by spraying or dipping the TLC/HPTLC layer with a universal or group-specific reagent. Sometimes 'destaining' techniques can improve sensitivity where such reagents are employed. Where complex mixtures of large numbers of analytes of differing functionality are involved, sequencing reactions can be used to locate groups of compounds progressively.

The most used and dependable reagents are discussed in detail below, however, this represents only a small fraction of the detection reagents available, and the literature should be consulted for a more comprehensive review. In choosing the best detection reagent, the following points should be borne in mind:

1. Sensitivity of detection.
2. Selectivity of the reagent for the analytes of interest.
3. Background effects, particularly where plates are to be scanned spectrophotometrically.
4. Stability of detection reagent.
5. Stability of the chromatogram after chemical or thermal treatment.
6. Ease of preparation of the spraying or dipping reagent.
7. Hazards associated with the use of particular detection reagent.

Universal chemical reagents

Iodine vapour/solution Iodine reacts chemically with unsaturated compounds, which is rarely reversible on silica gel layers. Also irreversible oxidations, electrophilic substitutions, addition reactions, and the formation of charged transfer complexes have been observed. The so-called 'iodine reaction' is possibly an oxidation with the initial formation of a radical cation as shown in the following reaction equation:

A number of possible reaction pathways can then occur. **Table 1** lists some of the common reactions

that take place on the chromatographic layer with iodine. Iodine also possesses fluorescence quenching properties, hence, chromatographic zones that contain iodine will appear as dark zones on a silica gel layer containing a fluorescent indicator when viewed under UV light at 254 nm.

In the case of both reversible and non-reversible reactions with iodine vapour, the chromatographic zones can be 'fixed' by further treatment with a 0.5–1.0% aqueous starch solution. The well-known deep blue iodine–starch complex is formed, which has good stability. As the reaction is very sensitive it is important to make sure that little iodine remains in the background, otherwise the whole background will be coloured blue!

The detection limits are usually a few micrograms of substance per chromatographic zone, but there are some cases where the detection is lower still (e.g. 200 ng glucose). Iodine may also be applied as a solution and is usually prepared in an organic solvent, such as petroleum spirit, acetone, methanol, chloroform or diethyl ether. A suitable dipping solution would be 250 mg iodine in 100 mL petroleum spirit. Such solutions have the advantage that, in some cases, the iodine is enriched to a greater extent in the chromatographic zones when dissolved in a lipophilic environment than a hydrophobic one. Hence, the sensitivity can be improved.

Ammonia vapour Ammonia vapour has a number of uses in chromatographic zone detection:

1. When pH indicator solutions are used to detect aliphatic and aromatic carboxylic acids and fatty acids, ammonia vapour can help to intensify the colours against a contrasting background (often a reversible reaction).

Table 1 Examples of iodine reactions on the TLC layer with a common range of organic substances

Substance	Reaction
Polycyclic aromatic hydrocarbons, indole and quinoline derivatives	Formation of oxidation products
Quinine alkaloids, barbiturates and calciferol	Addition of iodine to the double bonds
Opiates, brucine, ketazone and trimethazone	Iodine addition to the tertiary nitrogen for the opiates Addition reaction with the $-OCH_3$ group of the brucine Ring-opening reaction in the case of the ketazone and the trimethazone
Thiols and thioethers	Oxidation of sulfur and addition across the double bond in the thiazole ring
Alkaloids, phenthiazines and sulfonamides	Complex formation

2. There are a number of instances where residual chemical detection reagent gives a background colour. Often exposure to ammonia vapour has the apparent effect of bleaching it from the layer. (An example of this is in the use of molybdophosphoric acid reagent, where the background yellow colour is removed.) This effect increases sensitivity of detection.
3. Stabilization of some reactions on the layer is also possible with ammonia vapour. An instance of this is the blue colour of tryptamine after reaction with Gibb's reagent.

Nitric acid vapour Most aromatic compounds can be nitrated with the fumes from fuming nitric acid. The reaction works best if the developed chromatogram is heated to about 160°C for 10 min and introduced whilst still hot into a chamber containing the nitric acid vapour. Generally the chromatographic zones are rendered yellow or brown in colour. They also absorb in UV light at 270 nm. Some substances such as sugars, xanthine derivatives, testosterone and ephedrine fluoresce yellow or blue when excited by long wavelength UV light after such treatment.

Group specific reagents Many reagents give specific reactions with certain organic chemical groups and are called group-specific reagents. In most cases, the reaction mechanism is clearly understood. As a general rule these reagents are very sensitive. It is these reagents that make up the major part of the detection reagent lists that are readily available in a large number of TLC publications. The relative merits of a few of the major group-specific reagents are discussed below.

Oxidation/reduction reactions Often the most frequently used visualization techniques, oxidation/reduction reactions are group-specific depending on the particular reagent used. Some examples of oxidation reactions used in TLC are as follows: Emerson reagent (4-aminoantipyrine–potassium hexacyanoferrate [III]) for detection of arylamines and phenols; phosphomolybdic acid reagent for lipids and some steroids; chlorine–*o*-toluidine reagent for vitamin B₁, B₂, B₆ and triazines; chloramine T reagent for steroids and purine derivatives; and chlorine–potassium iodide–starch reagent for amino, imino and amido groups, and triazine herbicides. Examples of reduction reactions include: tin(II) chloride–4-dimethylaminobenzaldehyde reagent for the detection of aromatic nitrophenols; blue tetrazolium reagent for corticosteroids, Tillman's reagent (2,6-dichlorophenolindophenol) for organic acids including vit-

amin C; and silver nitrate–sodium hydroxide reagent for reducing sugars and sugar alcohols.

Hydrazone formation The reagent mainly employed for hydrazone formation is 2,4-dinitrophenylhydrazine in acidic solution, which provides a specific reagent for carbonyl compounds (aldehydes, ketones and carbohydrates). Yellow or orange-yellow hydrazones, or osazones in the case of carbohydrates, are formed on the chromatogram. Ascorbic acid and dehydroascorbic acid also respond to this reagent. The sensitivity limit is of the order of 10 ng per chromatographic zone.

Dansylation Dansyl chloride and other derivatives are used to produce fluorescent dansyl derivatives of amino acids, primary and secondary amines, fatty acids and phenols. The dansylation of fatty acids is indirect as the acid amides must be formed first. This conversion is readily achieved with the reagent dicyclohexylcarbodiimide. In the next step, dansyl cadaverine or dansyl piperidine is used to form fluorescent derivatives of the amides. The detection limit is 1–2 ng fatty acids.

Diazotization Azo dyes are strongly coloured and can be produced on the TLC layer by reduction to primary aryl amines, diazotization and coupling with phenols. Conversely, phenols can be detected by reaction with sulfanilic acid in the presence of sodium nitrite (Pauly's reagent). The coloured zones formed by such reactions are often stable for a period of months.

A few named reagents exist that rely upon a diazotization reaction to detect specific groups of compounds. Two well-known ones are the Bratton–Marshall reagent and Pauly's reagent. The Bratton–Marshall reagent consists of two spray solutions: the first, is sodium nitrite in acid to effect the diazotization; and the second is a mainly ethanolic solution of *N*-(1-naphthyl)ethylenediamine dihydrochloride. This reagent is used specifically to visualize primary aromatic amines, sulfonamides and urea, and carbamate herbicides. Pauly's reagent is used to visualize phenols, amines, some carboxylic acids and imidazole derivatives.

Metal complexes The cations of a variety of transition metals are electron acceptors and are therefore capable of forming complexes with colourless organic compounds that are electron donors. Coloured complexes are the result caused by electron movement within the orbitals of the central metal ion. The most important of these metal ions that form chelates are Cu²⁺, Fe³⁺ and Co²⁺, which have particular affinity

for compounds that contain oxygen and nitrogen. Examples of this type of chemistry are the biuret reaction with proteins (resulting in the formation of a reddish-violet complex) and the reaction of the Cu^{2+} ion with aromatic ethanolamines (to form blue-coloured chelates). In addition there is the formation of reddish-violet colours of phenolic compounds with the Fe^{3+} ion.

Schiff's base reaction The Schiff's base reaction is a group-specific reaction for aldehydes. The reaction usually occurs under basic conditions with aromatic amines to form a Schiff's base. Aniline is normally used to form a coloured anil or Schiff's base with an aldehyde. Carbohydrates can be visualized with 4-aminobenzoic acid with the formation of coloured and fluorescent Schiff's bases. A similar reaction mechanism occurs with 2-aminobiphenyl for aldehyde detection. One of the most sensitive reagents for reducing sugar visualization, the aniline phthalate reagent, is also a Schiff's base reaction. The limit of sensitivity is 10 µg per chromatographic zone.

Other reactions There are a number of less well-used reactions such as halogenation with bromine or chlorine vapour, esterification of alcohols, hydrolysis reactions, and the formation of charge transfer complexes. Many other popular reagents do not fit into the above categories, yet they do constitute a major part of visualization reagent lists. For some of these, the reaction mechanism has not been fully elucidated. Table 2 lists a selection of visualization reagents together with the classes of compounds visualized.

Sequencing reactions If it is known that particular functional groups may be present in the separated chromatographic zones, then reactions can be ex-

ploited more specifically, not necessarily to give direct identification, but to increase the evidence of the presence or absence of particular analytes. Here, specific reagent sequences can be used to give a wealth of evidence visually. Sequencing reactions are particularly useful where a number of differing functional group compounds are present on a chromatogram. An example illustrating the use of four well-known detection reagents is shown in Figure 1.

Where excess of one reagent has been used that may then interfere with the next reagent in the sequence, washing or 'destaining' steps will be necessary. Rinsing troughs in the form of dipping chambers can be used. Such sequential reactions are always carried out either to prepare a substance for a colour reaction that will follow later or to increase the amount of information that is obtained by exploiting a combination of different independent reactions. Therefore, information is provided that could not be obtained using a single reagent step.

Pre-chromatographic derivatization to enhance detection Group-specific reagents can prove very useful not only in detection but also in determining to some extent the choice of mobile phase for the development of the separation. If we are looking to determine the concentration of a particular compound, or similar compounds with the same functional group in a complex mixture, then prechromatographic derivatization with a group-specific reagent is an effective way of accomplishing this. The derivatization reaction is normally carried out before application of the sample to the chromatographic layer. Lengthy extraction procedures on sample preparation columns to clean up the sample before chromatography are not necessary. Such derivatizations are simple 'test tube' reactions, which usually are not time consuming.

Table 2 Popular visualization reagents for TLC

Visualization reagent	Compound groups visualized
Anisaldehyde-sulfuric acid	Terpenes, steroids, glycosides
Berberine	Fatty acids, triglycerides
Copper(II) acetate-phosphoric acid	Lipids, prostaglandins
Diphenylboric acid-2-aminoethyl ester	Flavonoids, carbohydrates
Dragendorff reagent	Alkaloids and other nitrogen-containing compounds
Ehrlich's reagent	Amines, indoles
Folin and Ciocalteu reagent	Phenols
Gibb's reagent	Phenols, indoles, thiols, barbiturates
Ninhydrin	Amino acids, peptides, amines, amino-sugars
Pinacriptol yellow	Alkyl and aryl sulfonic acids
Potassium hexaiodoplatinate	Alkaloids, nitrogen compounds, thiols
Thymol-sulfuric acid	Sugars, sugar alcohols
Vanillin-sulfuric acid	Essential oils, steroids

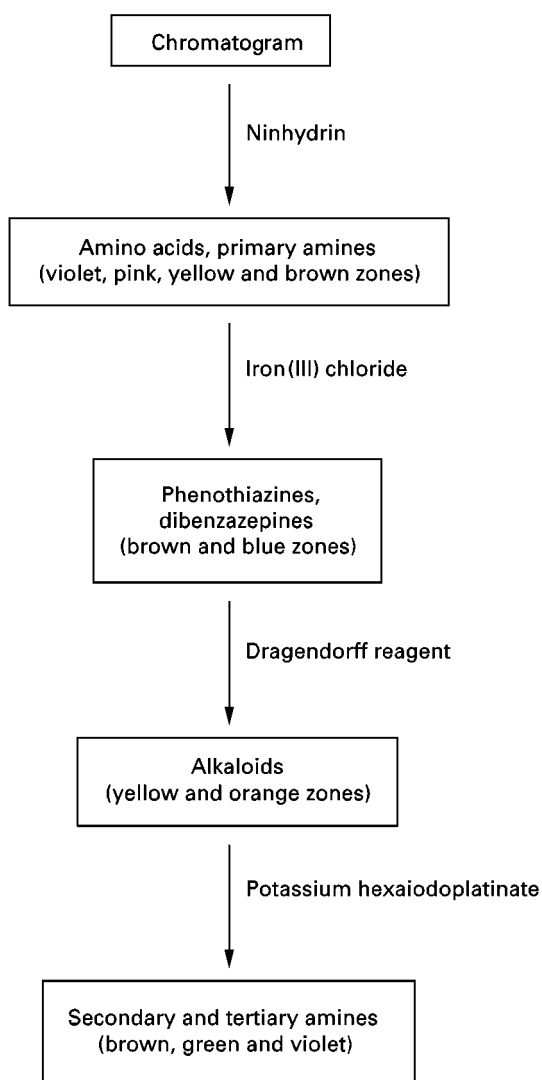

Figure 1 A typical visualization sequence for a TLC chromatogram. The sequence enables the identification of a number of different groups of nitrogen function organic compounds.

An example of such an analytical procedure is the determination of vitamin C in fruit juices. Although it is possible to apply the fruit juices directly to the TLC/HPTLC layer, develop the plate in a suitable solvent mixture, and then use a detection reagent to locate the vitamin C, a more precise and better resolution of the vitamin C can be achieved by derivatizing the sample first with 2,4-dinitrophenylhydrazine to form hydrazones with the keto groups ($>C=O$) present. The sample applied to the plate is then observable by its yellow colour. Using an appropriate solvent mixture for development, the yellow chromatographic zones can be visually observed as they separate and become resolved from each other.

An even more elegant and simple way to achieve prechromatographic derivatization is to carry out the reaction on the layer. At the point where the sample is

to be applied on the chromatographic layer, the derivatization reagents can also be applied. Either the sample can be applied to the layer first, followed by the derivatization reagent shortly afterwards, or it can be done in the reverse order. The advantage of applying the derivatization reagent first is that a complete track across the width of the adsorbent layer can be applied, resulting in complete reaction with the sample when it is dosed, usually as bands, on top of the derivatization reagent. After appropriate drying and reaction time, development of the chromatogram can proceed using a solvent mixture that takes into consideration the polarity of the newly formed compounds.

It is also possible to carry out such 'functional chromatography' within the framework of 2-dimensional separations. The first ascending development is carried out in the usual way with underivatized sample. Before the second development, the separation track is subjected to treatment with a detection reagent specific to the functional group present in the substances (e.g. acids can be esterified, alcohols can be oxidized to ketones or aldehydes, carbonyls can be reduced to alcohols, carbonyls can form hydrazones or semicarbazones). The second development then follows in the usual way at 90° to the first.

Spraying Versus Dipping

Reagents can be applied to TLC/HPTLC plates either by dipping or spraying. The advantages and disadvantages of these approaches are considered below.

Spray Devices

A number of spray devices have been in use for many years. Perhaps the oldest is the atomizer spray, an all-glass unit that uses a rubber bulb to hand pump air into the main unit, which disturbs the detection reagent sufficiently to provide a fine spray out of the exit nozzle. More sophisticated versions have used propellant canisters to provide the means of atomizing the reagent solution into tiny droplets, which can then be evenly sprayed on to the chromatographic layer. As spray guns are relatively inexpensive, they tend to be the most popular spraying devices. However, it is important that the plastic components of the spray gun that come into contact with the detection reagents are solvent resistant. Spray canisters used to contain low-boiling CFCs as propellants, but now contain low-boiling, low-flash point hydrocarbons. More recently, rechargeable electro-pneumatically operated spray systems have become commercially available (an example is shown in **Figure 2**). The basic equipment consists of two spray heads with two different diameter capillaries, together with a charger and spray holder. The smaller diameter

Figure 2 (See Colour Plate 33) An electropneumatically operated spray system for TLC. (Reproduced with the permission of Merck Ltd., UK.)

capillary (0.8 mm) is designed for spraying alcoholic or other low-viscosity solutions, whereas the larger diameter capillary (1.25 mm) is used for more viscous reagents like sulfuric acid. It can, of course, also be used to spray low viscosity reagents at higher rates.

Immersion Devices

In the last few years, dipping or immersion devices for TLC and HPTLC plates have been gaining in popularity. There are obviously benefits with regards to the handling of harmful, irritant or toxic chemicals, but also the uptake of reagent on to the chromatographic layer can be better controlled by immersion.

Chambers for immersion devices need to be as narrow as possible to limit the amount of reagent required, but not so narrow that the chromatographic layer is damaged by contact with the vessel. Manual dipping can be employed, but it is important that the chromatogram is fully dipped and the motion of dipping is done in one constant motion, otherwise 'tide' or 'contour'-like marks will appear on the layer. These will usually interfere with any further spectrophotometric evaluation.

For good reproducibility and reliable constant uptake of reagent into the chromatographic layer, automated immersion devices are essential (an example is shown in Figure 3). These allow precise control of the time of immersion and the rate of dipping, which is essential for good reproducible results.

Future Prospects

The last decade has seen a move away from the use of spray reagents to immersion devices. This trend will inevitably continue as the hazards associated with the spraying of chemical reagents, many of which contain harmful substances, can be avoided by dipping. The greater control over the visualization process that dipping affords is also something that will be encouraged as the whole TLC technique becomes more standardized. Although many chemical reagents are already available, it is likely that new group-specific reagents will be discovered, often replacing those that contain toxic chemicals.

It is in the area of sequencing reactions where probably the greatest growth will occur as only a

Figure 3 A commercial immersion device for automatic dipping of TLC chromatograms in visualization reagents. (Reproduced with the permission of CAMAG, Switzerland.)

limited number of protocols are presently available. The visualization of the many different types of compounds present in herbal products may well drive the research required.

Pre-derivatization of sample on the TLC plate is proving to be a technique that often results in excellent resolution of analytes of interest. It is to be expected that further protocols will be developed in this area on the basis of reaction sequences that may already be available.

Tables showing the detection of compounds on TLC plates following chromatographic development can be found in appendix 17 on page 4801.

Introduction

Thin-layer chromatography (TLC) is a simple technique, many runs can be performed at the same time on a single plate, no detection problems occur provided a suitable reagent is used and moreover all solutes are detected. The main drawback is that a good detecting device designed for quantitative work is as expensive as a complete HPLC apparatus.

The observed decline of TLC is mainly due to the belief that efficiency is poor. To perpetuate that idea,

qualitative data are obtained when no care is taken to carry out experiments! The advent of nanoplates coated with fine particles has given a renewed interest in the technique as excellent separations have been reported. By analogy to HPLC (high performance liquid chromatography) the acronym HPTLC (high performance thin-layer chromatography) appeared in the literature. Unfortunately different claims of performance have been published and some misunderstanding between pro and anti HPTLC camps have arisen, leading to fruitless discussions.

In their first paper, Rippahhn and Halpaap reported height equivalent to one theoretical plate (HETP) as low as 15 μm with these nanoplates; on the other hand Delley and Szekely cut a 'normal TLC' plate in four parts to yield the size of nanoplates and obtained identical results. The data of Rippahhn and

Halpaap are effectively comparable to those obtained by HPLC. To compare geometrically different systems, reduced or dimensionless parameters must be used: $h = H/d_p$, the reduced HETP in which H is the observed HETP and d_p the particle diameter. As often no improvement in separation efficiency is observed with HPTLC plates, it is worth reconsidering all the parameters involved in efficiency. Extensive work has been carried out on liquid column chromatography and a proper use of the technique has been defined. The purpose of this article is to consider what is possible or not, which plates are to be used and how to shorten analysis time.

Basic Equations

The aim of the analyst is the complete separation of two (or more) solutes. The resolution of two consecutive Gaussian chromatographic bands is given by:

$$R_s = \frac{2(x_1 - x_2)}{\omega_1 + \omega_2} \quad [1]$$

where x_1 and x_2 are the migration distances of solutes 1 and 2, respectively and ω_1 and ω_2 are base widths of the spots.

If we call L the migration distance of the solvent front, then:

$$R_F = \frac{x}{L} \quad [2]$$

The plate number is given by:

$$N = 16\left(\frac{x}{\omega}\right)^2 = 16\left(\frac{R_F L}{\omega}\right)^2 = \frac{R_F L}{H} \quad [3]$$

Neglecting the variable density of the liquid phase along the plate due to the wide distribution of pore size in the TLC bed, the retardation factor is related to the bed capacity factor through

$$R_F = \frac{1}{1 + k} \quad [4]$$

where k is the retention factor (see HPLC).

The actual relationship is more complex because R_F is somewhat dependent on the experimental conditions, an effect which is neglected as a first approximation. Chromatographers use either R_F or k , depending upon whether they are interested in column or thin-layer chromatography. The parameter α , the relative retention of the two consecutive solutes of interest is given by:

$$\alpha = \frac{k_2}{k_1} = \frac{K_2}{K_1} \quad [5]$$

where K is the well-defined equilibrium constant

$$\frac{\alpha - 1}{\alpha} = \frac{\Delta K}{K} = \frac{R_{F2} - R_{F1}}{R_{F2}(1 - R_{F1})} \quad [6]$$

and

$$\frac{\Delta K}{K} = \frac{\Delta R_F}{R_{F2}(1 - R_{F1})} \quad [7]$$

in which R_{F1} is the smaller retention factor.

When the two spots are close together, $R_{F1} \cong R_{F2}$, and

$$\frac{\Delta K}{K} = \frac{\Delta R_F}{R_F(1 - R_F)} \quad [7a]$$

The resolution is then given by:

$$R_s = \frac{\sqrt{N}}{4} \times \frac{\Delta K}{K} (1 - R_F) \quad [8]$$

According to Snyder, the number of theoretical plates, N , observed in TLC is related to R_F as follows:

$$N = N' \times R_F \quad [9]$$

N' is called the bed efficiency, or the number of hypothetical theoretical plates observed with an inert solute. The Snyder equation is thus written:

$$R_s = \left(\frac{\sqrt{N'}}{4}\right) \left(\frac{\Delta K}{K}\right) (1 - R_F) \sqrt{R_F} \quad [10]$$

From this equation it is impossible to achieve any resolution when R_F is 1 or 0. **Figure 1** shows a plot of the variation of resolution, R_s , with R_F . A maximum is observed when $R_F = 0.33$. However, within the range 0.20–0.50 no dramatic loss of resolution occur as 92% of the maximum efficiency is reached. It is essential to select a solvent that gives an R_F value somewhat larger than 0.33 for the two solutes to be separated, in order to achieve the analysis within a reasonable time.

Rewriting eqn [10] in a more convenient form yields:

$$R = \frac{\sqrt{N}}{4} \times \frac{\Delta R_F}{R_F} \quad [11]$$

R_F is a function of both the ratio of the equilibrium constants K_1 and K_2 of the two solutes and of the plate characteristics. ΔR_F is not a simple measurement of the difficulty of a separation.

Figure 1 Variation of the resolution between two compounds with the retention of the second compound of the pair. ($R_{F1} \cong R_{F2}$). The figure is drawn assuming that

$$\frac{\sqrt{N'}}{4} \left(\frac{\alpha - 1}{\alpha} \right) = 1$$

thus $R_i = (1 - R_F) \sqrt{R_F}$. (Reproduced with permission from Guiochon G and Siouffi A (1979) *Journal of Chromatographic Science* 16: 368–386.)

The necessary plate number to achieve a given separation is well known in column chromatography:

$$N_{ne} = 16 R_S^2 \left(\frac{\alpha}{\alpha - 1} \right)^2 \times \left(\frac{1 + k}{k} \right)^2 \quad [12]$$

and is written here as:

$$N_{ne} = 16 R_S^2 \left(\frac{\alpha}{\alpha - 1} \right)^2 \times \frac{1}{(1 - R_F)^2} \quad [13]$$

The problem is to achieve N_{ne} with minimum effort and maximum convenience. It is more complicated than in column chromatography as nothing can be done about the speed of the eluent. This flow rate is obviously not constant and we shall consider the laws governing flow rate in TLC in the next section.

Flow Velocity of the Mobile Phase

In normal practice a thin-layer plate is immersed in a tank filled to a height z_0 with the developing solvent. It has been shown that the migration of the mobile phase in a thin-layer plate may be compared to penetration of a liquid by diffusion in interconnected capillaries. A liquid enters a capillary because in doing so it decreases its free energy and more molecules

diffuse from the liquid to the wall of the capillary tube.

The height of ascent, z_M , is governed by two forces acting on the liquid: capillary rise and hydrostatic pressure.

$$z_M = \frac{2\gamma \cos \theta'}{\rho g r} \quad [14]$$

where γ is the surface tension, r is the radius of the capillary, ρ is the density of the solvent, and θ' is the wetting angle.

The smaller the radius, the higher the ascent, and thus smaller particles will govern the rise of eluent. An order of magnitude of r is the radius of the largest sphere that can fall through the hole between three tangent spheres of diameter d_p , i.e. $d_p/15$. Equation [14] does not say anything, however, about the kinetics of the phenomenon.

According to Poiseuille's law, the flow rate in a capillary is given by:

$$Q = \frac{-\pi r^4}{8\eta} \times \frac{\delta P}{\delta x}$$

where η is the viscosity of the liquid and $\delta P/\delta x$ is the pressure gradient along the tube.

As particles are of different sizes and r is not constant, there will obviously be a higher resistance to flow through the smaller tubes. The bulk of the flow will be through the larger capillaries, which fill more slowly behind the solvent front. Thus the volume of liquid is not evenly distributed along the plate; the wet area near the solvent front contains less liquid. A simple glance at a developing plate reveals this fact. In selected experiments the capillary rise can be monitored by UV recording of suitable solvents or, much better, by X-ray absorption. In this latter case the saturation of the porous layer is measured as a function of time and the relationship between the logarithm of the transmitted intensity I and the liquid content is linear. In all cases a plot similar to that of Figure 2 is obtained.

Figure 2 Filling of the layer by the solvent during the course of development.

In consequence we shall not consider further solutes that move at the same speed as the solvent front, as the profile of such a spot would be irregular.

Experimentally the analyst looks at the sharp line separating wet and dry layers. Initially we shall assume that there is no loss of solvent by vaporization and no uptake of vapours by adsorption. It is usually accepted that the distance between the solvent front and the solvent source z_f is related to elapsed time by a quadratic equation:

$$z_f^2 = k_v t \quad [15]$$

k_v is called the velocity constant and depends on the chromatographic system. Thus:

$$k_v = -2b \frac{P_e}{\eta} \Delta P_c \quad [16]$$

where b is the proportionality constant between the rate of advance of the front dz_f/dt and the local flux of mobile phase different from unity.

The term P_e is the permeability of the porous bed given through the Kozeny equation by:

$$P_e = \frac{\varepsilon^3 d_p^2}{180(1-\varepsilon)^2} = P_0 d_p^2 \quad [17]$$

in which ε , the external bed porosity, is the ratio of the volume of interparticle space to the volume of the layer bed.

ΔP_c is the capillary pressure change from the adsorbent saturated with liquid to the dry bed. ΔP_c is proportional to γ , the surface tension of the mobile phase, and inversely proportional to d_p .

$$\Delta P_c = \frac{\gamma}{d_p} \cos \theta' \quad [18]$$

and from eqn [16]

$$k_v = -\frac{2bP_0\gamma}{\eta} d_p \cos \theta' \quad [19]$$

The geometrical factor b has been found to be around 0.8. An expression for k_v in the migration of a liquid in a granular layer has been proposed:

$$k_v = \frac{2bP_0 d_p}{\eta} \left[\gamma \cos \theta' - z_f \frac{d_p \rho g}{12} \right] \quad [20]$$

This assumes that $r = d_p/6$, which is rather large (but the pores of different particles do not connect directly) and it is found that $b = 1$.

Figure 3 Variation of the velocity constant with the ratio γ'/η for a series of solvents on HPTLC plates; LiChrosorb 5 μm (Merck E, Darmstadt, Germany). (Reprinted with permission from Guiochon G and Siouffi A (1978) *Journal of Chromatographic Science* 16: 598–609.)

Incorporating b into P_0 gives:

$$z_f^2 = \frac{2P_0 d_p \gamma \cos \theta'}{\eta} t = \text{constant} \times t = k_v t \quad [21]$$

The validity of this equation is now well established. As early as 1968, Stahl plotted z_f^2 versus t and obtained a straight line. Stewart had already demonstrated the proportionality between k_v and γ/η . These early experiments were carried out either on paper or on thin layers made with a rather large particle size distribution. More precise data can be gathered from measurements carried out with layers of a narrow particle size distribution (Figure 3).

From the slope of the line the value of P_0 may be derived. Table 1 lists some values obtained with plain silica assuming perfect wettability by solvent so that $\cos \theta' = 1$.

These data from either commercial or homemade plates are in excellent agreement. The coating procedure does not play a significant role and the binding agent has apparently no influence on the hydrodynamics of the plate. In the same way intraparticle

Table 1 Experimental values of P_0

Origin of data	Values of P_0
Stahl	6.7×10^{-3}
Guiochon and Siouffi	8.15×10^{-3}
Ripphahn and Halpaap	6.7×10^{-3}

pore dimensions have no effect as there is no marked difference between Si 60 and Si 100 silica of the same particle size. An experiment was performed on very wide pore silica (Si 50 000) and the velocity constant was the same as the speed was very rapid. The average P_0 value (8×10^{-3}) is rather large when compared to column chromatography (1×10^{-3}).

The proportionality of the velocity constant to the particle diameter has been checked with carefully sorted silica particles and excellent agreement is obtained.

It is convenient to introduce a coefficient of velocity θ , is given by:

$$\theta = \frac{k_v}{d_p} \quad [22]$$

This gives a parameter independent of d_p , which is easier to take into account when calculating the velocity of the eluent in beds made with particles of different diameter. The utility of θ will become apparent in the following sections.

The main drawback of TLC is the presence of a gas phase in contact with the eluent, which yields deviations from the ideal flow velocity. How to get reproducible retention data has given rise to a huge volume of literature. Many practical methods of operations are possible: some workers use saturated tanks in which blotter pads are placed and a certain amount of developing solution is poured over the pads; some workers use nonequilibrated tanks where the plate is placed inside the tank and developed immediately, in contrast to equilibrated tanks where plates are placed in the tank an hour prior to development. Whatever method is used, the presence of the gas phase will influence the solvent front rise through adsorption or vaporization.

Effect of Solvent Vaporization

The observation of most TLC spots shows that solute distribution is not uniform. Precise data have been collected by Hezel and Belenkii, who used a microtome to cut layers 0.05 mm thick. There is a radial flow of liquid phase, which explains why the material in spots is on the surface of the plate, the band being thinner than the layer itself. When a plate is wetted by the mobile phase, vaporization occurs, the flux of which ϕ_v , is given by:

$$\phi_v = \nu l z_f \quad [23]$$

where l is the width of the plate and ν is the rate of vaporization per unit surface area.

ν is the function of $P^0 - P$, the difference between the vapour pressure P^0 of the solvent and its partial

pressure P (if the gas phase is homogeneous, otherwise calculations would be nearly impossible).

The flow of solvent leaving the solvent source, ϕ_s , is proportional to both the cross-sectional area of the layer, el (where e is the thickness of the layer bed), and the aspiration speed, u .

$$\phi_s = elu = \frac{k_v el}{2z_f} \quad [24]$$

The actual flow rate is therefore:

$$el \frac{dz_f}{dt} = \phi_s - \phi_v \quad [25]$$

By combination of the above equations and rearrangement:

$$2z \frac{dz_f}{dt} + \frac{2\nu}{e} z_f^2 - k_v = 0 \quad [26]$$

Integration of this second-order equation and two terms expansion gives:

$$z_f^2 \cong k_v t - \frac{k_v \nu}{e} t^2 = k_v t \left[1 - \frac{\nu}{e} t \right] \quad [27]$$

Equation [27] is valid if the rate of vaporization is small compared to the flow rate inside the layer bed. This is true since from Van Brakel's data the evaporation expressed in terms of the velocity of the rising front is about 0.5 mm day^{-1} with toluene or water. A loss of $1\% \text{ min}^{-1}$ is reasonable.

Effect of Adsorption

Adsorption acts in the opposite direction to vaporization. The building of a monomolecular layer of solvent vapour on the surface of the adsorbent, followed by the appearance of a multilayer adsorption film and possible capillary condensation in the smallest pores when the partial pressure is large, reduces progressively the layer porosity (for example from 0.75 to 0.50 within 15 min).

Let $\varepsilon_{T,0}$ be the bed porosity of the dry adsorbent and $\varepsilon_{T,t}$ the porosity at time t when adsorption has begun:

$$\varepsilon_{T,t} = \frac{V_t}{Se} = \varepsilon_{T,0} - \frac{\nu' t}{e} \quad [28]$$

Here V_t is the total free volume at time t , given by

$$V_t = V_0 - S\nu' t \quad [29]$$

where S is the layer surface area and ν' is the adsorption rate defined in the same way as ν .

To move by dz_f during dt , the solvent front must be supplied by a volume

$$dV = \varepsilon_{T,t} e l dz_f \quad [30]$$

coming from the solvent source and so:

$$dV = \varepsilon_{T,0} e l u \quad [31]$$

Equating expressions for dV gives

$$\varepsilon_{T,t} dz_f = \varepsilon_{T,0} u = \varepsilon_{T,0} \frac{k_v}{2z_f} \quad [32]$$

Combination of the above equations using the same procedure as above gives:

$$\begin{aligned} z_f^2 &= -\frac{k_v \varepsilon e}{v'} \log \left[1 - \frac{v't}{e} \right] \\ &\cong k_v t \left[1 + \frac{v'}{\varepsilon e} t \right] \end{aligned} \quad [33]$$

General Equation

In the classical situation both adsorption and vaporization occur and thus:

$$\frac{2z_f dz_f}{dt} + \frac{2v}{e\varepsilon_t} z_f^2 - \frac{\varepsilon}{\varepsilon_t} k_v = 0 \quad [34]$$

$$z_f^2 = \frac{\varepsilon k_v e}{2v} \left[1 - \left(1 - \frac{v't}{e\varepsilon} \right)^{2v/v'} \right] \quad [35]$$

When $v' = 0$ eqn [27] is valid as $\varepsilon_{T,0}/\varepsilon_{T,t} = 1$. When $v = 0$, eqn [33] is obtained. Integration yields

$$z_f^2 = k_v t \left[1 + \frac{v' - 2v}{2e\varepsilon} t \right] \quad [36]$$

Figure 4 displays the general case when both adsorption and (or) vaporization can occur.

In every case when the development is kept short there is no marked deviation from the quadratic law. A very curious situation arises when $v' = 2v$ as then exact compensation of adsorption is made by vaporization.

Practical Aspects

Plots such as in Figure 4 are quite difficult to obtain and calculations from these curves may be tedious. An easier way is to plot z^2/t versus t , which yields a straight line as shown in Figure 5.

Curve 4 has a negative slope, which means that vaporization predominates. From the slope $k_v v/e$ (k_v

Figure 4 Combination of adsorption and vaporization. Layer thickness, 0.01 cm; velocity constant $k_v = 0.0235 \text{ cm}^2 \text{ s}^{-1}$; porosity of the dry layer, 0.75.

Curve 1 Adsorption speed $v' = 2 \times 10^{-5} \text{ cm s}^{-1}$, vaporization speed $v = 0$. The particles are filled at A ($\varepsilon_t = 0.40$). The total porosity is 0.30 at C, 0.20 at D and 0.10 at E.

Curve 2 $v' = 0$, $\varepsilon_t = 0.4$, $v = 0$, eqn [21] is applied.

Curve 3 $v' = 0$, $v = 1 \times 10^{-5} \text{ cm s}^{-1}$.

Curve 4 $v' = 6 \times 10^{-6} \text{ cm s}^{-1}$, $v = 0$. The particles are filled at B ($\varepsilon_t = 0.40$). The porosity is 0.30 at F.

Curve 5 $v' = 0$, $v = 0$, curves 2 and 5 coincide.

Curve 6 $v' = 0$, $v = 1 \times 10^{-5} \text{ cm s}^{-1}$. (Reprinted with permission from Guiochon G and Siouffi A (1978) *Journal of Chromatographic Science* 16: 598-609.)

is known from the ordinate of the plot, e by plate fabrication) the determination of v is possible (see Table 2). With benzene and toluene (curves 1 and 2) a slight positive slope is observed, which means adsorption. The 'best' curve is curve 3, corresponding to carbon tetrachloride. It should be pointed out that measurements are very imprecise on short development (1 cm or less) as it is difficult to check accurately the solvent front. Table 2 displays the data gathered from Figure 5.

A developing solvent must be carefully chosen. Besides the retention requirements it is necessary to discard solvents that may give high adsorption or vaporization rates. Some properties of common TLC solvents compiled from Rippahhn and Halpaap and

Figure 5 Plots of z^2/t versus t with different solvents on plain silica, $d_p = 5 \mu\text{m}$. Layer thickness 0.2 mm, porosity ε 0.80. Solvents: 1, benzene; 2, xylene; 3, carbon tetrachloride; 4, dichloromethane. (Reprinted with permission from Guiochon G and Siouffi A (1978) *Journal of Chromatographic Science* 16: 598–609.)

our own data are reported in Table 3. θ has been normalized to 5 cm development distance. It is worth checking the time necessary to fill the particles with solvent when adsorption predominates. This time

Table 2 Deviations from the quadratic law (plates 0.2 mm thick of silica Si 60)

Solvent	Curve in Figure 5	$v' - 2v$ (m s^{-1})
Benzene	1	3×10^{-8}
Toluene	2	3×10^{-8}
Carbon tetrachloride	3	0.8×10^{-8}
Dichloromethane	4	-1.3×10^{-8}

may be calculated from:

$$t_s = \frac{\varepsilon - 0.4}{v'} \times e \quad [37]$$

and may be compared with the time needed for the solvent to move by 10 cm (t_3).

With diethyl ether, for example, $t_s > t_3$ (see Table 3); with *n*-pentane, chloroform, dichloromethane and ethyl acetate t_3 is between the time necessary to fill an internal porosity of 0.35 and one of 0.40. A correlation should be possible between v' and P^0 , but this relation is not linear. It is unfortunate that most TLC

^aTime t_3 ($z = 10$ cm) is larger than the time necessary to fill the inside of particles in a bed of inner porosity 0.35 (see text).

^bFor these solvents $t_s > t_3$.

data only quote R_F and no information is given on the velocity constant as is usual in HPLC.

Effect on R_F

When adsorption is predominant, the liquid moves inside a layer with constant porosity while the solvent front moves through a layer of decreasing porosity. The front velocity u is different from the bulk velocity u_b . The apparent retention factor $R_{F,a}$ is by definition:

$$R_{F,a} = \frac{x}{z_f} = \frac{z(\text{spot})}{z(\text{solvent})}$$

$$z_f = ut$$

$$x = u_b R_{F,t} t \quad (R_{F,t} \text{ is the true retention factor})$$

$$R_{F,a} = \frac{u_b}{u} \times R_{F,t}$$

$$\frac{u_b}{u} = \frac{\varepsilon_t}{\varepsilon} = \frac{\varepsilon - v't/e}{\varepsilon} = \frac{1 - v't}{\varepsilon e} \quad [38]$$

and thus

$$R_{F,a} = R_{F,t} \left(\frac{1 - v't}{\varepsilon e} \right) \quad [39]$$

R_F can also be modified, and to a much larger extent by modification of the surface activity as a consequence of adsorption of solvent vapour or more active vapours such as water, which it is almost impossible to eliminate from the tank atmosphere.

$R_{F,a}$ may thus be different from one run to another; this is the plague of TLC! Experiments carried out in either equilibrated or saturated tanks decrease $R_{F,a}$. Evidently, time of development is shorter, for example 63 min are necessary for a 10 cm development in an unsaturated tank and only 48 min in a saturated one. Dhont has studied the influence of vapour preadsorption on stability of R_F and showed that equilibrium may require several hours. Adsorption of methyl isobutyl ketone prior to development decreases $R_{F,a}$ from 0.35 to 0.22. Adsorption or vaporization may be decreased to a considerable extent by use of sandwich quasicolumn systems as advocated by Soczewinski or Tyihak.

Reversed-Phase Plates

The number of available stationary phases in TLC is not very large. Silica is still widely used and some separations are better carried out on alumina, cellulose or polyamide. In the above discussion, data were compiled from experiments made with silica on

Table 4 Velocity constants, rate of adsorption, and wetting angles from TLC data with pure organic solvents

Solvent	$k_v \times 10^4 \text{ (m s}^{-1}\text{)}$	$v' \times 10^8 \text{ (m s}^{-1}\text{)}$	$\cos \theta'$
<i>n</i> -Pentane	6.5	4.8	0.87
<i>n</i> -Heptane	4.9	6.0	0.94
<i>n</i> -Dodecane	1.7		0.82
Toluene	4.8	6.4	0.96
Chlorobenzene	3.6	5.3	0.83
Bromobenzene	2.4	5.4	0.71
Acetonitrile	6.1	4.3	0.75

which the contact angle θ' is very large and thus $\cos \theta' = -1$. Alkyl-bonded silica plates are readily available and the number of published separations on these supports is rapidly increasing. These bonded silicas are hydrophobic and some velocity constants with pure organic solvents are given in Table 4.

These data were gathered from plates with average particle size $6.5 \mu\text{m}$ and an assumed P_0 of 7.9×10^{-3} . Apolar solvents completely wet the layer but polar solvents exhibit values of $\cos \theta'$ much lower than 1. These TLC data are consistent with those published by Riedo *et al.* from capillary rise in Pyrex tubes treated with octadecyltrimethyl silane. There is no evident correlation between $\cos \theta'$ and a physical property such as dielectric constant or ability to form hydrogen bonds.

With such plates water-organic solvent mixtures are used and a plot of the cosine of the contact angle versus the water concentration in a water/ethanol eluent is shown in Figure 6.

Figure 6 Plot of the cosine of the contact angle versus the water concentration of a water/ethanol mixture. ●, home made plates; ○, Merck plates (no spacer); □, Merck plates (with 1.5 mm spacer). (Reprinted from Guiochon G, Korosi G and Siouffi A (1979) *Journal of Chromatographic Science* 18: 324–329.)

Figure 7 Plot of time necessary to ascend 4 cm versus percentage of water in mixtures of methanol/water and acetonitrile/water. ●, acetonitrile; ○, methanol. Plate LiChrosorb RP-18 (7 μm).

The value of $\cos \theta'$ decreases rapidly as the percentage of water increases. When θ' is close to 90° the solvent is unable to ascend the plate. Even when using a relatively nonviscous organic solvent such as acetonitrile, 30% of water is the upper limit.

In Figure 7, the variation of 4 cm development time with percentage of water is reported, showing the very steep rise of the curve. Analysis may last more than 1 h, which is undesirable. The differences that occur with chain length are rather small but the sequence $\text{RP } 2 < \text{RP } 8 < \text{RP } 18$ is observed. A compromise between the extended hydrophobicity of a totally modified RP phase and the strong hydrophilic character of unmodified silica has been found with layers prepared with a lower degree of silanization. These layers are completely water wetttable (WF plates) and permit the ascent of mobile phases with high water content.

Band Broadening and Plate Height Equation

The Different Parameters

As has been shown above, the speed of the eluent is a complex function of time and space and will not give the desired constant flow rate as in HPLC. Accordingly the plate efficiency is also a complex function of experimental conditions.

According to Giddings, we can use the definition of the local plate height H_l as the proportionality constant between the differential increase in the variance of a Gaussian profile spot and the differential length of migration:

$$H_l = \frac{d\sigma^2}{dx} \quad [40]$$

The average plate height may be defined as:

$$\bar{H} = \frac{\int_0^x H_l dx}{\int_0^x R_F dx} = \frac{\sigma^2}{(z - z_0)R_F} \quad [41]$$

z and z_0 have been previously defined and $(z - z_0)R_F$ is the migration distance of the solute; σ^2 is the variance of the spot to which the contribution due to the starting spot width should be added.

We shall here treat the TLC plate as being equivalent to a normal chromatographic column bed: it is homogeneous, there is one dimensional flow (no vaporization or adsorption). This may seem oversimplified, but most conclusions apply in practice, giving some validity to the model.

We use the conventional Knox reduced plate height equation:

$$h = \frac{B}{v} + Av^{1/3} + Cv \quad [42]$$

where v is the reduced velocity (ud_p/D_m). Here A , B and C are dimensionless coefficients with reference to packing density (A), mass transfer (C) and diffusion (B).

In liquid column chromatography A characterizes the quality of the packing and is usually between 1 and 5; $A = 1$ corresponds to a very good packing. Much work has been done to prepare excellent columns and even now manufacturers each have their own procedure. To our knowledge nothing has been seriously done to improve the packing in TLC, probably because it is easier to achieve a good two-dimensional bed than a three-dimensional one. No precise data on packing in TLC are available but we may suppose a small value of A . The C term characterizes the mass transfer inside the particle. It comes from diffusion in the stagnant mobile phase, kinetics of adsorption-desorption, etc. C varies with R_F (or k) for a given chromatographic system. An average value of 0.01 will be used in most calculations. The B term is mainly a diffusion term. In GC the diffusion in the stationary phase is considered as negligible since the diffusion in the gas phase is several orders of magnitude higher (10^5). In liquid chromatography, the situation is different and the contribution to axial

diffusion resulting from molecular diffusion in the stationary phase may become of the same order of magnitude as the contribution of molecular diffusion in the mobile phase. A rigorous treatment has been published by Giddings and we thus write:

$$B = 2 \left[\gamma_m D_m + \left(\frac{1 - R_F}{R_F} \right) \gamma_s D_s \right] \quad [43]$$

D_m and D_s are diffusion coefficients in the mobile and stationary phases, respectively; γ_m and γ_s are the tortuosity coefficients of the packing and the porous particle, respectively. We shall assume that $\gamma_s \cong \gamma_m$ and assume the same value as in classical column chromatography of 0.7.

Going to a dimensional equation, the local plate height is:

$$H_l = \frac{B D_m}{u} + \frac{A d_p^{4/3}}{D_m^{1/3}} u^{1/3} + \frac{C d_p^2}{D_m} u \quad [44]$$

As

$$u = \frac{\theta d_p}{2z} \quad [45]$$

we can write:

$$H_l = \frac{B D_m}{\theta d_p} z + \frac{A \theta^{1/3} d_p^{5/3}}{(2 D_m)^{1/3}} z^{-1/3} + \frac{C \theta d_p^3}{2 D_m z} \quad [46]$$

We can use eqn [46] to integrate eqn [41].

As we are interested in the chromatographic process we shall consider that the initial spot has a negligible width. This is obviously not true but we can always correct for it using variance addition. In eqn [46], z is the distance of front migration and the integration variable is given by:

$$x = R_F z \quad \text{so that} \quad dx = R_F dz$$

$$H = \int_{z_0}^L \frac{H_l R_F dz}{(L - z_0)} \quad [47]$$

Integration yields:

$$\begin{aligned} \bar{H} = & \frac{B}{\theta d_p} [L + z_0] + \frac{3 A d_p^{5/3} \theta^{1/3}}{2 (2 D_m)^{1/3}} \frac{L^{2/3} - z_0^{2/3}}{L - z_0} \\ & + \frac{C \theta d_p^3}{2 D_m (L - z_0)} \log \frac{L}{z_0} \end{aligned} \quad [48]$$

This equation is difficult to handle and may be rewritten for the sake of simplicity as:

$$\bar{H} = B'(L + z_0) + \frac{A'}{L - z_0} (L^{2/3} - z_0^{2/3}) + \frac{C'}{L - z_0} \log \frac{L}{z_0} \quad [49]$$

where

$$B' = \frac{2 \gamma D_m}{\theta d_p} \quad [50]$$

$$A' = \frac{3}{2} A \frac{d_p^{5/3} \theta^{1/3}}{(2 D_m)^{1/3}} \quad [51]$$

$$C' = \frac{C \theta d_p^3}{2 D_m} \quad [52]$$

It may appear surprising that in such a form eqn [46] does not depend on R_F , but it must be remembered that B depends on R_F and when $\gamma_s D_s$ is close to $\gamma_m D_m$, $B' = 2 \gamma D / \theta d_p R_F$.

A , C and γ are coefficients that depend on the plate itself and are constants. The terms A' , B' and C' do not contribute to \bar{H} in equal ways but they all depend on D_m , d_p and θ .

Influence of D_m Diffusion coefficients depends on the solute. D_m is usually calculated through the Wilke Chang equation:

$$D_m = 7.4 \times 10^{-10} \times \sqrt{\psi_s M_s} \frac{T}{\eta V_i^{0.6}} \quad [53]$$

where M_s is the molecular weight of the solvent, ψ_s an association constant depending on the nature of the solvent (1 for nonassociating solvents, 2 for strong hydrogen-bonding solvents), and V_i is the molar volume of the solute.

High molecular weight solutes will exhibit a low diffusion coefficient. Some values of D_m have been selected to cover the whole range of classical solutes (we have excepted polymers or very low molecular weight compounds that are analysed by SEC or GC, respectively) and values of A' , B' and C' have been computed for a given chromatographic system (d_p , θ , R_F). These values are reported in Table 5.

It is clear from the above data that the B' term is the most important one when the diffusion coefficient is large; its influence decreases slowly as D_m decreases. The plate height increases rapidly with diffusion coefficient (Figure 8). With small particles, H is linearly dependent on L and thus B' is the only term that governs efficiency. This efficiency decreases sharply as L increases. In other words, solutes of high D_m will be poorly separated on small particles with a rather long migration length.

When $d_p = 20 \mu\text{m}$, the situation is completely different. Provided the development length is long enough, all solutes will be separated in the same way,

Table 5 Effect of changing diffusion coefficient on the coefficients of the HETP equation

D_m ($\text{m}^2 \text{s}^{-1}$)	$A' (\times 10^4)$	$B' (\times 10^4)^a$	$C' (\times 10^6)$
3×10^{-9}	4.36	25.4	0.983

3×10^{-10}	9.40	2.54	9.83

Chromatographic conditions: $A = 1$; $C = 0.01$; $10^{-2} \theta = 47.2 \text{ m s}^{-1}$; $z_0 = 0.5 \text{ cm}$; $R_F = 0.7$; $\gamma = 0.7$; $d_p = 5 \mu\text{m}$.

^aAssuming $B' = 2\gamma D_m / \theta d_p R_F$.

a situation that does not occur with small particles. The most interesting feature is that H may be smaller with $20 \mu\text{m}$ particles than with $5 \mu\text{m}$ ones. A dotted round on the curves indicates the length of development when coarse particles become more efficient than fine particles.

Influence of retention From eqn [49], R_F is only involved in the B' term. If R_F is the only variable and the other parameters are kept constant, then we can write:

$$H = \beta \left[D_m + \frac{1 - R_F}{R_F} D_s \right] + \mu + \Gamma \quad [54]$$

As μ, β, Γ are kept constant, a plot of H versus $(1 - R_F)/R_F$ or retention factor would be linear. Such

**Figure 8** Plot of HETP versus development distance showing the effect of diffusion coefficient. Curves 1–4 $d_p = 5 \mu\text{m}$. Curves 5–8 $d_p = 20 \mu\text{m}$.

Particle size $5 \mu\text{m}$. 1, $R_F = 0.9$; 2, $R_F = 0.8$; 3, $R_F = 0.7$; 4, $R_F = 0.5$; 5, $R_F = 0.3$; 6, $R_F = 0.2$. (Reprinted with permission from Guiochon G and Siouffi A (1978) *Journal of Chromatographic Science* 16: 470–481.)

plots can be drawn from data already published and are shown in Figure 9. The fit of a straight line is excellent as long as solutes are not strongly retained, i.e. when $(1 - R_F)/R_F$ is not too large.

Influence of particle size Examination of D_m has shown that different performances may be attained depending on whether fine or coarse particles are considered. Tables 6 and 7 together with Figure 10 allow the comparison of the different terms A' , B' and C' with d_p .

Best efficiencies are obtained with small particles if D_m is small and development length is short. H will increase very rapidly with increasing length of plate if very fine particles are used. If migration is long the coarser particles are more efficient, which is particularly evident from the plots. We have an explanation for the different claims of efficiencies: most demonstrations of HPTLC are made using mixtures of dyes that have rather large molecular weights and low D_m s. Although the nanoplate size prevents long development, some early chromatographers performed development for too long a distance so that efficiency was less than with the older TLC plates. Moreover, the optimal velocity of solvent ($v \cong 3.8$) is kept constant for quite a long time with coarse particles but only for a short time with fine particles. As was

Table 6 Effect of change in particle size on the coefficients of the HETP equation

50	368.0	0.424	5.90×10^3

Chromatographic conditions: $A = 1$; $C = 0.01$; $\theta = 47.2 \text{ cm s}^{-1}$; $z_0 = 0.5 \text{ cm}$.

$a\gamma = 0.7$; $R_F = 0.7$; $D_m = 5 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$. B' is assumed to be $2\gamma D_m/\theta d_p R_F$.

demonstrated in HPLC, the race towards finer and finer particles looks meaningless in TLC for the development ought to be so short that the variance of sample deposition would be too large by far. On the other hand 15 μm particles appear to be a good compromise between efficiency and development length. From these results it is also obvious that one requirement of high performance TLC is the use of particles with a narrow size distribution. The mobile phase velocity is determined by the fine particles and efficiency by the coarse ones, so that one loses on both counts.

Table 7 Effect of change in particle size on coefficients of the HETP equation

d_p (μm)	$A' \times 10^4$	$B' \times 10^4$	$C' \times 10^5$

Chromatographic conditions as for Table 6, except $D_m = 1 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$.

**Figure 10** Plot of HETP versus development distance showing the effect of particle diameter. Diffusion coefficient, $5 \times 10^{-6} \text{ cm}^2 \text{ s}^{-1}$. Numbers on curves represent particle size (μm).

Influence of velocity coefficient θ It is difficult to select a convenient liquid that keeps the critical solute within the R_F range of 0.30–0.60. From the previous conclusions θ must be as large as possible, but θ is imposed by the choice of the chromatographic system and little can be done to change it.

Relative role of the different contributions to band broadening From the above calculations it is clear that the mass transfer C' only plays a minor role unless the plate is poorly prepared or made with very coarse particles, which are not used in current practice. It thus may be neglected in almost all cases, as shown in Figure 11, which gives variation of A' , B' and C' when $d_p = 5 \mu\text{m}$ or— $d_p = 20 \mu\text{m}$ for a given D_m .

As expected from previous discussions, the B' term is often the only one which must be taken into account. For $d_p = 5 \mu\text{m}$ the packing term is only 0.25 H at $L = 1 \text{ cm}$ and 0.03 H at $L = 10 \text{ cm}$. In contrast, it accounts for 0.9 H when $L = 1 \text{ cm}$ and $d_p = 20 \mu\text{m}$. When development distance increases the contribution of molecular diffusion increases as the contribution of packing decreases. Molecular diffusion and packing irregularities are equal when the following condition is satisfied:

$$\frac{L^{2/3} - z_0^{2/3}}{L^2 - z_0^2} = \frac{4\sqrt[3]{2}}{3R_F} \frac{\gamma}{A} \left(\frac{D_m^4}{\theta^4 d_p^8} \right)^{1/3} \quad [55]$$

The balance between these two major contributions may be achieved for particles in the 7–15 μm range with a reasonable development length (3–15 cm).

Figure 11 Different contributions to the apparent HETP versus development length. Curves 1, 2 and 3 correspond to particle size 5 μm . Curves 4–7 correspond to particle size 20 μm . Curves 1 and 4, total plate height. Curves 2 and 5 show the contribution of molecular diffusion. Curves 3 and 6 show the packing contribution, while curve 7 shows the mass transfer contribution (this last contribution is too small to be represented when $d_p = 5 \mu\text{m}$). $D_m = 1 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$. (Reprinted with permission from Guiochon G and Siouffi A (1978) *Journal of Chromatographic Science* 16: 470–481.)

The H versus L Curve

Collection of experimental data in TLC is much more difficult than in HPLC where a single column can supply much information whereas, the development of many TLC plates is needed for the same purpose.

The relationship between H and L has been checked with small particles carefully sorted; the results are shown in **Figure 12**. The scattering of experimental points on both sides of the theoretical straight line is the consequence of the lack of reproducibility from one plate to another and mainly from the spot shape. The original spot is too large for its contribution to the final spot width to be neglected. It may be corrected but it must be remembered that a Gaussian profile of the injection spot is almost impossible to achieve. Be that as it may, the H versus L line is well predicted by theory.

We used data from Halpaap and Krebs to check our own results. No information was provided on solutes and particle size but the knowledge that ordinary TLC plates are made from 11–15 μm particles

and HPTLC plates from 5–7 μm particles, and that lipophilic dyestuffs are high molecular weight molecules of $D_m \cong 6 \times 10^{-6} \text{ cm}^2 \text{ s}^{-1}$, was used to plot H versus L as shown in **Figure 13**. The fit is not perfect but the main feature is well predicted by theory.

Brinkman has carried out an experimental verification of our conclusions. He performed TLC of solutes of very different D_m such as chloroanilines and dyestuffs. With chloroanilines, he observed a very steep increase in H with development length. To quote Brinkman: ‘a similar steep increase is absent in conventional TLC’. With the dyestuffs the difference between the curves is not so large.

As predicted, the efficiency is better with HPTLC plates over a small development length.

In the same way Tyihak found a striking agreement between observed and theoretical curves and checked experimentally that TLC plates are more efficient than HPTLC plates for a 10 cm development distance.

A careless comparison between experimental and theoretical curves could lead to some fallacies. Experimental plots exhibit a minimum plate height,

Figure 12 Variation of plate height with development length. Mixture of bis chlorophenyl triazine isomers; solvent CCl_4 . Silica 7 μm particle diameter. ■, $R_F = 0.28$; ○, $R_F = 0.58$. Figure 13 Plots of H versus L from data of Halpaaf H and Krebs KF (1981) *Journal Chromatography* 209: 129–147. Dyestuffs: \circ , violet ($D_m = 6 \times 10^{-6} \text{ cm}^2 \text{ s}^{-1}$; $R_F = 0.75$; $C = 0.10$); \square , green ($D_m = 6 \times 10^{-6} \text{ cm}^2 \text{ s}^{-1}$; $R_F = 0.45$; $C = 0.20$); \triangle , blue ($D_m = 4 \times 10^{-6} \text{ cm}^2 \text{ s}^{-1}$; $R_F = 0.17$; $C = 0.20$).

Experimental points and curves were calculated with $\theta = 70 \text{ cm s}^{-1}$, $\gamma = 0.75$, $A = 0.80$ and $d_p = 15 \mu\text{m}$ for TLC plates. (A) $A = 1.0$ and $d_p = 7 \mu\text{m}$ for HPTLC plates. (B) Curves: 1, blue; 2, green; 3, violet. The lower curves in (B) correspond to the assumption that $\gamma_s D_s = 0.5 \gamma_m D_m$ and all others correspond to $\gamma_s D_s = \gamma_m D_m$. (Reprinted with permission from *Journal of Chromatography*.)

which is not predicted by theory, and measured H are higher than calculated. Currently available spectrophotodensitometers are inadequate to detect carefully a spot of very short migration because their response time is too large, the light spot is too large, and the scanning speed too quick. Halpaap and Ripphahn have corrected the data they published. In Figure 14 we assumed an independent contribution to the spot width. Evidence suggests that experimental data cannot fit theoretical calculations with very short development length because of the lack of a special instrument. This misadaptation of detecting device is a further explanation for the poor efficiency often observed.

Conclusion

In HPLC the analyst carefully selects optimum mobile phase velocity to obtain the lowest HETP and the highest plate count. In TLC the situation is more

difficult to handle. Most often, mobile phase velocity is not considered with much attention and this may lead to erroneous conclusions based solely on observed R_F values. Adsorption or vaporization can dramatically affect retention and it is of the greatest importance to standardize experimental conditions to get reproducible results. A glance at a TLC figure caption is often deceptive since it is rare that information is gathered on the time taken by the solvent front to ascend the plate, the position of the spot above the solvent level (z_0), etc.

Since the mobile phase velocity is not constant the classical HETP equations (van Deemter equation in GC or Knox's equation in HPLC) do not apply. In TLC the HETP equation is of the H versus development length type.

With TLC, low HETP may be generated but the final performances do not compare with HPLC. Nanoplates coated with small particles can provide good performances with short development

Figure 14 Variation of plate height with development length. Solute: Desaga yellow ($M = 225$); $D_m = 1.37 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$; $R_F = 0.80$. Solvent: toluene; $\theta = 77$. Packing: silica ($d_p = 11 \text{ }\mu\text{m}$).

Curve 1 Theoretical curve calculated with $\gamma = 0.7$, $A' = 2.48 \times 10^{-3}$, $A = 1$, $B = 2.8 \times 10^{-6}$, $C' = 0.11 \times 10^{-4}$, $C = 0.03$.

Curve 2 curve calculated by adding a constant equipment contribution to the spot variance ($\sigma_{eq} = 4.3 \times 10^{-3} \text{ cm}^2$). (Reprinted with permission from Guiochon G and Siouffi A (1978) *Journal of Chromatographic Science* 16: 470–481.)

distances. The analyst's task is to consider the characteristics of solutes to separate (particularly the diffusion coefficient) and the particle size of the available plates. Then he or she can select the correct plate and the correct development distance to achieve the separation if the plate count is reached under those conditions. It must be remembered that in this article we have only considered the chromatographic experiment. We have not considered extra band broadening from injection (which is important in TLC) or detection devices.

Appendix: Symbols used

b proportionality constant of eqn [16]
 d_p mean particle diameter

e thickness of the layer bed
 h reduced HETP
 k retention factor
 k_v velocity constant
 l width of the plate
 r radius of the capillary
 t time
 t_3 time needed for the solvent to move 10 cm
 u velocity of the solvent front
 u_b velocity of the bulk of the solvent
 v rate of vaporization per unit surface area
 v' adsorption rate
 x_i migration distance of solute i
 z_f distance between the solvent front and the solvent source
 z_M height of capillary ascent
 z_0 height of liquid in the tank

A, B, C constants in the Knox equation
 A', B', C' coefficients in the Guiochon equation
 D diffusion coefficient of the solute
 D_m diffusion coefficient of the solute in mobile phase
 D_s diffusion coefficient of the solute in the stationary phase
 H plate height
 H_1 local plate height
 K equilibrium constant
 L migration distance of the solvent or effective plate length
 M_s molecular weight of the solvent
 N plate number
 N' bed efficiency
 N_{ne} plate number to achieve a given separation
 P_e permeability
 P_0 specific permeability (does not depend on particle size)
 P partial pressure of the solvent
 P^0 vapour pressure of the solvent
 Q flow rate in the capillary
 R_F retention factor in TLC
 $R_{F,a}$ apparent retention factor
 $R_{F,t}$ true retention factor
 R_S Resolution between two consecutive peaks (or spots)
 S layer surface area
 V_i molar volume of the solute
 V_t total free volume at time t

α selectivity or relative retention
 γ surface tension of the mobile phase
 γ_m, γ_s tortuosity coefficients in the mobile (m) and stationary (s) phases
 ε bed porosity

$\varepsilon_{T,0}$	bed porosity of the dry adsorbent
$\varepsilon_{T,t}$	external porosity at time t
ΔP_c	capillary pressure change
η	viscosity of the solvent
θ	specific velocity constant of the solvent
θ'	wetting angle
v	reduced velocity
ϕ_v	flow of solvent vaporized from the wet part of the bed
ϕ_s	flow of solvent across the bed cross-section immediately above the solvent level in the tank
ψ_s	association constant of a solvent
ρ	solvent density
ω_i	base width of spot i

Introduction

Crystallization is the nucleation and growth of a solid phase in a mother liquor. It can be used as a separation technique, because the process results in the separation of the mother liquor and the solid phase. If the mother liquor and the solid phase have different compositions it can also be used as a purification technique. In such cases the mother liquor must contain impurities. The deliberate addition of impurities during the crystallization process, has been widely used to improve both the product quality and the process performance. However, most impurities present during crystallization processes are not added on purpose, but are by-products from previous reactions, dissolved salts and solvents that can have the same kinds of effects.

In industrial crystallization additives are generally used to improve the handling characteristics of the crystalline product or to prevent scaling. By employing correctly selected additives it is possible to reduce caking, improve the free flowing behaviour of a powder, increase the bulk density of a crystalline product, change the crystal size distribution, induce certain polymorphs and improve filtration behaviour.

Varied though this list may seem, all these effects can be achieved by using additives that have very specific interactions with the crystal surface. This fundamental physical effect causes a change in the system parameters when additives are introduced. Detailed knowledge of the molecular structure of the solid-liquid interface is very important for design of additives. Once this interface is understood, it is possible to design molecules that have specific interactions with one or more of the faces of a crystal. Often the same additive can be used in different application. For instance a growth retarder used to prevent scaling of a given compound can, when added after crystallization, also act as an anticaking

agent. Blocking a single crystal face with a certain additive can induce morphology changes, but the same additive can also be used to act as a template for the nucleation of that same crystal face.

In many cases additives are not wanted in the product application. Ferrocyanide is a very effective anticaking agent for salt (NaCl), but the ferrocyanide complex must be destroyed and the iron precipitated prior to electrolysis of the salt for the production of chlorine (Cl_2). Nitrosyltriacetamide is also an effective anticaking agent for salt, but during electrolysis nitrogen trichloride (an explosive) is formed.

Apart from having a very specific influence on a crystal face, additives must also be effective at very low concentrations. Because one of the main uses of additives is in cheap bulk products (costing less than US \$1 kg^{-1}) the price of the additive also acts as an incentive to keep the additive concentrations as low as possible. Expensive additives, even if used in very low amounts, will adversely affect the cost of these cheap bulk products. High additive concentrations always give rise to significant additive incorporation in the crystal and thus decrease the product purity.

Additives that effectively control crystallization processes are also found in nature: the shells of crustaceans are formed as a result of bio-templated growth of calcium carbonate; the growth of the mineral components of our bones and teeth is carefully regulated; and studies of fish in polar regions have revealed some proteins that very effectively block the growth of ice crystals.

After describing the fundamental effects of the additive in the crystallization system, a general procedure for the molecular design of additives will be given. The review ends with some case studies.

Interaction of Impurities and Crystal Surfaces

The effect of an impurity that is present in small quantities (parts per million (ppm) level) cannot be explained solely by its effect on solution bulk parameters such as solubility. The phenomenon that is at the root of all the effects of impurities on process performance and product quality is the interaction of the impurity with the crystal surfaces.

Adsorption of the impurity can take place on flat surfaces, at stepped surfaces and at kink sites (Figure 1). The adsorbed compound can impede the movement of steps on the surface. This is a kinetic effect and causes a reduction in the growth rate of the corresponding crystal surface. For instance the induction time, i.e. the time that elapses until the outgrown nuclei are detectable, can increase because the outgrowth of nuclei takes longer.

Origin and Type of Impurities

In solution crystallization the solvent is an inevitable impurity. Additives play a role in the improvement of product quality (e.g. shape of the crystals, crystal size distribution) or process performance (e.g. filterability). One source of impurities in the crystallization process is the synthesis of the crystal compound, as synthesis by-products greatly affect crystallization.

Impurities can also be classified based on their character. Apart from organic and inorganic compounds, a special group of impurities is the polyelectrolytes, long carbon chain molecules with many functional groups. Because of the large number of functional groups the interaction between polyelectrolytes and crystal surfaces is strong. The large number of functional groups also makes the molecule kinetically very hard to remove, as all the bonded functional groups have to be detached from the surface. One of the detached functional groups remaining bonded to the polyelectrolyte and is thus positioned very near the crystal surface. The attachment of that one functional group onto the surface is faster than the detachment from the surface of the other functional groups of the polyelectrolyte molecule. The strong interaction and the large number of interaction points make polyelectrolytes highly effective additives at very low concentrations. Another special group of impurities is the crystallizing compounds themselves. Long chain hydrocarbons such as fats may cause self-poisoning on certain surfaces if the fat molecules in the melt near the surface have a different conformation from the fat molecules in the surface.

Figure 1 Additive adsorption at various positions on a crystal surface: 1, flat surface; 2, step; 3, kink site.

Predicting the Effects of Impurities

The deliberate addition of an impurity is intended to cause a particular effect, such as a reduction in mineral scale formation or a change in morphology. This effect comes from changes in the kinetic process involved, e.g. for a change in morphology the relative growth rates of the different crystal faces have to change. The function of the additive is thus very specific: the morphology changes if the growth of a specific face is blocked. This is illustrated in Table 1 for a number of desired additive effects. The first column gives the desired effect, the second the kinetic process involved and the third the action acquired by the additive. Table 2 shows whether an interaction with a specific face or all faces is required, at what particular moment the additive should be added and whether it blocks a face or acts as a template. This table shows the close relationship between additives used for different purposes. An anticaking agent is simply an antiscaling agent added after crystallization, and an additive used to block a specific crystal face can in some cases also act as a template for that same face.

Identification of an unintentional impurity and understanding of its effect on the crystallization process requires a kind of reverse engineering. Many impurities are formed as by-products during the synthesis of the compound to be crystallized. By observing how the crystallization process changes in the presence of impurities, the kinetic process involved can be identified. The effect on the process then can be matched with the expected (predicted) effect of one of the impurities present. This is a rather complicated procedure because not all the impurities present that can act on the kinetic processes involved will be known.

The desired effects of additives are changes in the crystal quality or the process parameters. The crystal quality is an overall term for a variety of crystal parameters (morphology, purity, etc.). Changes in the process conditions due to additives, such as better filterability, make the process more efficient. Figure 2 shows the effects of the impurities on the crystal quality and the process conditions. The working directions for both the rational design and the reverse engineering are shown. Key to this figure is knowledge of the interaction of a given compound with the crystalline interface. This interaction determines whether an impurity can, e.g. block growth or induce nucleation of a given face. After evaluating the influence of a given impurity on the morphologically most important faces, the overall effect on the crystal growth and the outgrowth of

Table 1 Additive effects on the crystal growth process

<i>Desired effect</i>	<i>Kinetic process involved</i>	<i>Action required</i>
Anticaking	Dissolution and regrowth of crystalline material	Complete blocking of growth
Antiscaling	Complete blocking of nucleation and/or growth	Complete blocking of growth
Changing morphology (filtration, flowability)	Ratio of growth rates of different faces	Block specific faces
Control of polymorphism	Nucleation of a given polymorph	Mimicing a face of the desired polymorph
Changing crystal size distribution	Changing nucleation/growth ratio	Block specific faces, or block all faces

nuclei can be deduced. From these effects the influence on the crystal quality and the product handling characteristics and ultimately the product properties can be determined. The starting point for designing and studying additives is therefore a study of the molecular structure of the crystalline interface.

Molecular Structure of the Crystal Surface

Both the impurity and the crystal surface determine the strength of the interaction. A crystal has several crystal surfaces, which might have totally different molecular structures. Crystal faces are identified by Miller indices, which indicate how the faces are cut from the crystal unit cell. **Figure 3** shows a unit cell and two crystal surface structures for the compound RDX (cyclotrimethylene trinitramine) with different Miller indices. Since the molecular structures are very different, the interactions of the impurity with the surfaces might also be very different. The growth of one face might be blocked because of strong interactions, while the other face can grow freely because the interactions are only minor. This can cause face-specific growth retardation.

Prediction of the Molecular Structure of the Crystalline Interface

A morphology can be geometrically constructed by drawing planes with an orientation (*hkl*) having a dis-

tance from the origin proportional to the growth rate. The central volume enclosed by the set of planes is the growth form. A face with a large growth rate is positioned far from the origin, and thus its surface area will be small. In contrast, a face with a small growth rate will be close to the origin and have a large surface area (**Figure 4**). This means that the morphology is determined by the slowest growing (*hkl*) faces and that a morphology prediction can be made if the relative growth rates of all the different (*hkl*) faces are known.

Figure 4 also shows the effect of a growth-retarding impurity. Before a crystal face can grow the adsorbed impurity has to be removed from the surface. This takes energy, and thus the growth rate decreases. When face-specific adsorption occurs, surface concentrations of the impurity vary from face to face. The growth retarding effect will then also vary from face-to-face. When face-specific adsorption occurs, the relative growth rates may change, as shown in **Figure 4**.

Nowadays there are several general prediction methods for vacuum morphologies. Here vacuum means that the influence of the solvent or the melt is not taken into account. Donnay and Harker's law states that the importance of a crystal face decreases with interplanar distance d_{hkl} . A morphology can be predicted if the interplanar distance is assumed to be inversely proportional to the relative growth rate of the corresponding crystal face. A prediction method that takes into account the anisotropic energies in the

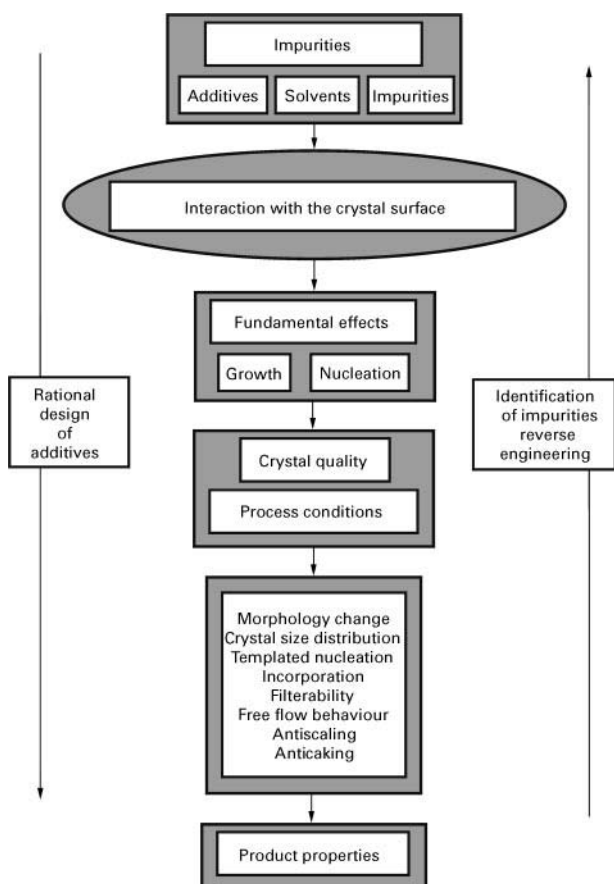

Figure 2 The interaction between the surface and the impurity is the key to the effect of the additive in the crystallization process. This effect translates to changes in the growth and nucleation behaviour of the crystal compound, which in turn affect the crystal quality and process parameters and thus the product properties change.

crystal unit cell is the attachment energy method. The attachment energy is defined as the energy release per growth unit upon adding a growth slice of thickness d_{hkl} onto the corresponding crystal surface. The assumption that the attachment energy is linearly proportional to the relative growth rate of the corresponding crystal surface gives the morphology prediction.

The Design Method

These vacuum morphology prediction methods do not take into account the actual growth processes taking place on a molecular scale at the crystal surfaces. Our goal is to predict the effect of an impurity that affects these growth processes. Such a method should include calculations of the interaction energy between the impurity and the surface. This interaction energy affects the molecular growth processes taking place at the surface.

To make such a prediction, knowledge must first be obtained about the crystal surface structures present. Simple energy calculations determine the morphologically important surface structures. Then more sophisticated calculation methods such as molecular mechanics, molecular dynamics, Monte Carlo techniques or even quantum mechanical calculation methods are needed to calculate the interaction energies of the morphologically important crystal surface structures with the impurity. These interaction energies can be translated into growth rates of the surface structures by assuming a model which interrelates growth rate and interaction energy. The general method for the design of additives is shown in Figure 5.

A good way of determining surface structures and their morphological importance is by performing a periodic bond chain (PBC) analysis. A PBC is an uninterrupted chain of strong bonds between growth units in which periodicity is based on the unit cell parameters and symmetry and which is stoichiometric with regard to the unit cell content. Two sets of intersecting PBCs make a connected net. The connected net can be considered a (hkl) growth slice or growth layer. If a surface does not contain a connected net, the surface cannot grow with a layer growth mechanism and is rough. This means that the relative growth rates of (hkl) surfaces that do not contain connected nets, are very large. These surfaces are not present on the crystal morphology, as a surface needs to contain a connected net to be present. If a surface contains more than one connected net (slices at different heights) more surface structures are possible for one crystal surface. Energy calculations should determine which of the surface structures actually occurs on the surface. However, it is important to remember that the morphologically important surface structure for a particular (hkl) surface may change because of interactions with impurities.

The morphologically important surface structures can be determined by calculating the attachment energy E_a of a surface slice containing a connected net from the bond energies in the slice (the slice energy E_{sl}) and the lattice energy E_{cr} . The attachment energies of all the possible surface structures can be used to determine the relative growth rates of these surface structures:

$$R \propto E_a = E_{cr} - E_{sl}$$

This results in morphologically important crystal surface structures for crystals grown from systems without boundary layer influences such as solvent interactions with the surface structures.

Figure 3 The RDX (cyclotrimethylene trinitramine) unit cell (top left), and the (2 0 0) and (0 2 0) slices, indicating their surface structure. For the (2 0 0) slice the connected net is given on the right of the molecular view of the slice while for the (0 2 0) slice the connected net is given below the molecular view of the slice, as they occur in the unit cell. The surfaces are given perpendicular to the paper. The dotted line in the molecular view of the surfaces indicates the surface.

Commercial software packages nowadays have several tools to calculate interaction energies of one or more impurity molecules on these surface structures.

Figure 4 The faces with the smallest growth rates determine the morphology. A growth rate decrease ($R_3 \rightarrow R'_3$) because of a face-specific interaction of the foreign compound causes a morphologically more important surface and thus a change in the morphology.

Once the interaction energies have been calculated, they should be related to the growth rates of the crystal surface structures. The models used for this relation are generally based on the assumption that interaction reduces the growth rate. First the impurity has to be removed from the surface before the face can grow. This takes energy and thus the growth rate decreases. An energy correction term E_s for the vacuum attachment energy can be introduced, which is a function of the interaction of the impurity and the flat crystal surface structure:

$$R \propto E'_a = E_a - E_s$$

In most cases only the interaction of a single ion, complex or molecule with the different crystal surfaces has to be considered. By determining the strongest interactions the corrected attachment energies can be calculated and changes in the morphology can be predicted.

By dynamically simulating a solvent layer on a surface structure (with either a molecular dynamics or a Monte Carlo procedure), the energy changes induced in the solvent layer by the presence of the

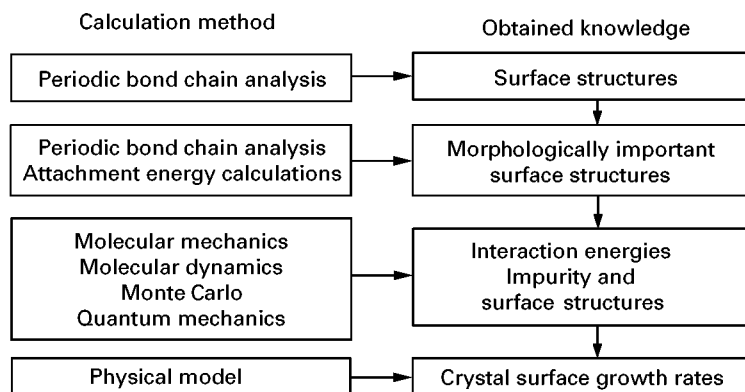

Figure 5 Method of calculating the effect of an impurity on the growth rates of the different crystal faces.

crystalline interface can be estimated, and thus the interaction energy E_s can be calculated. The procedure has to be repeated for all important faces. Though this procedure is somewhat tedious, it yields important insights as to how a solvent can influence the morphology.

Tailor-Made Additives

Tailor-made additives are usually organic additives that are especially designed to aid in the crystallization of a particular organic crystal compound. The additive can be designed to work only on a very specific crystal surface. Again, the additive works by blocking the growth of this crystal surface, making the surface morphologically more important. A characteristic tailor-made additive is very similar to a building unit. The interaction energies needed for adsorption of the building unit and the additive to the surface are similar. Therefore if the additive is adsorbed, it will be relatively hard to remove it from the surface. To retard the growth of the crystal surface, the additive molecule needs a functional group that differs from the growth unit. The functional group may be chosen so that the additive molecule still resembles the building unit, but is smaller. The tailor-made additive is then of the disruptive type. If, because of its functional group, the additive molecule is much larger than the building unit, the additive is of the blocking type (Figure 6).

The attachment energy of a growth unit that belongs to a certain crystal surface can be assumed to be linearly proportional to the growth rate of that crystal face. If the slice to be attached contains an additive, the slice energy changes. However, this change will be small if the additive strongly resembles the building unit (as is the case in both Figure 6B and Figure 6C: $E_{sl} \approx E_{sl}^d \approx E_{sl}^b$). Slices with tailor-made additives will also have a similar attachment energy:

$E_a \approx E_a^{d1} \approx E_a^{b1}$. The difference between crystallization with and without a tailor-made additive is the attachment energy of a subsequent normal slice onto the slice with the additive in it. This attachment energy (E_a^{d2} , E_a^{b2}) is decreased because of the functional group of the additive.

A disruptive type of additive will cause a decrease in the attachment energy E_a^{d2} compared with the normal attachment energy E_a because some bonds between the attaching slice and the surface cannot be made. Because the attachment energy decreases, the growth rate of the crystal surface decreases. During crystallization the disruptive additive can be incorporated in the lattice.

A blocking type of additive will cause a very large decrease in the attachment energy E_a^{b2} compared with the normal attachment energy E_a because the functional group of the additive interferes with the attaching slice. Either the additive has to be removed from the surface or vacancies have to be introduced in the attaching slice to allow the face to grow. This takes large amounts of energy, a large decrease in attachment energy, and thus leads to growth blocking. Instead of having a larger functional group,

Figure 6 Tailor-made additives can act as growth disrupters or growth blockers.

a blocking additive can also have a functional group that is differently charged from the growth unit, and therefore rejects an incoming growth layer.

This approach can also be used for reverse engineering to find an impurity in the system that causes problems such as incorporation in the lattice or inclusion formation, especially when synthesis by-products that strongly resemble the building units are known to be present as impurities. Disruptive impurities, which have a tendency to incorporate into the lattice, can be distinguished from blocking impurities, which can cause macrosteps and thus inclusion formation. Inclusion formation is the incorporation of pockets of mother liquor into the crystal. A crystal grown from a solution containing a blocking impurity is shown in **Figure 7**. Very large macrosteps are visible on the crystal, and small inclusions also appear in the interior of the crystal.

Incorporation of Impurities

Impurities obviously reduce the purity of the crystalline product and are seldom beneficial to the crystallization processes or the product characteristics. As with the design of additives, it is important to understand how the impurities are incorporated in the crystalline product to reduce their uptake.

In general an impurity is included in the crystalline product through either direct incorporation in the lattice (solid solubility), the formation of inclusions, surface adsorption or poor washing of agglomerates. These incorporation mechanisms will be discussed in more detail.

Solid solutions can only be formed when the impurities mimic the main compound in form and charge.

Figure 7 An RDX (cyclotrimethylene trinitramine) crystal grown from the solvent cyclohexanone. A blocking type impurity in the system causes very large macrosteps on a particular surface and inclusions in the interior of the crystal.

They are especially likely to occur with organic crystals where closely related by-products are formed during synthesis of the product. Examples are 2,6-dimethylnaphthalene in naphthalene, cyclohexanone in caprolactam and bromide in sodium chloride. This phenomenon can only occur when the crystallization enthalpy of the impurity is very close to that of the main compound. If that is the case, not only will the impurity be easy to include in the crystal lattice, but the growth will not be retarded. In other words, compounds that form high concentration solid solutions have a very limited influence on the growth of the main compound. If the impurity resembles the main compound to a lesser extent the solid solubility will decrease and growth will be hindered. The free enthalpy involved in the incorporation of polymers or polyelectrolytes, which are the most effective additives in mineral scale prevention, is so large that they are not incorporated in the lattice by direct substitution for molecules or ions of the main component.

A second incorporation mechanism is inclusion formation. Inclusions can be formed in several ways. The most common mechanism in industrial crystallization involves imperfect regrowth of corners damaged by attrition. Pockets of mother liquor are then trapped. The concentration of impurity in the inclusion is then directly related to the concentration in the mother liquor. The overgrowth of poisoned areas is another type of inclusion formation, and occurs at higher driving forces for crystallization. This is essentially the only way to overcome the blocking effects of polymers and polyelectrolytes. As discussed previously, the concentration of polymers or polyelectrolytes in solution is low because these additives are effective at low concentrations and most of the additive is adsorbed on the crystal surface. The amount of additive in the product will therefore not increase much, but of course the amount of other impurities present in the mother liquor, such as solvent, will increase.

A third incorporation mechanism is adherence to the surface. 'Normal' impurities, which cannot be incorporated in the lattice, can be washed off fairly easily. Tailor-made additives, however, are designed to adhere to the surface and are difficult to remove. Partial dissolution of the crystals is not an effective solution as these additives may also hamper the dissolution process. Washing is therefore very useful for the removal of 'normal' impurities, but less so for tailor-made additives.

The formation of voids in agglomerates on impurity uptake is a fourth mechanism of impurity uptake.

In conclusion, impurities that do not hinder crystal growth can be effectively removed from the

product through a combination of careful crystallization and after treatments (washing, etc.). Compounds such as tailor-made additives are much harder to remove.

Case Studies

To illustrate the general principles four cases will be discussed. These cases show the variety of possible applications of additives and the problems sometimes associated with the presence of impurities in the mother liquor. Scaling inhibition is demonstrated using barium sulfate as an example, diesel fuel additives illustrate how the crystal size distribution can be changed, crystallization of α -lactose is a good example of self-poisoning, and the template directed crystallization of calcium carbonate is also discussed.

Scaling problems are often encountered in oil production. The two major scaling problems involve gas hydrates and mineral scaling. Gas hydrates occur when methane and water crystallize under high pressure to form clathrate structures; this can happen in gas pipes on the bottom of the sea. These crystals can scale and block the pipes. Nowadays much research effort is put into the design of additives to prevent these clathrate crystals from blocking the pipes.

Mineral scaling occurs in secondary oil recovery. When the immediate vicinity of a borehole becomes depleted in oil, water is injected in the surrounding rock strata to push the remaining oil from the pores towards the borehole. The pores also contain water that at these deep levels contains a high concentration of barium. When seawater (which contains large amounts of sulfate) is injected, barium sulfate precipitates and the pores silt up. In the worst case the pores are plugged and a new hole must be drilled, which is a very costly operation. Scale formation is inhibited by the addition of low amounts (ppm levels) of polyelectrolytes, for instance polycarboxylates and polysulfonates. Experiments have shown that the molecular structure of the polyelectrolyte determines the effectiveness of the additive. Polyelectrolytes containing sulfonate or phosphonate groups, which closely resemble the sulfate groups in the crystal lattice, are more effective than polyelectrolytes containing only carboxylate groups. Also the way the sulfonate groups are attached to the backbone is important: molecules with the sulfonate group directly attached are more effective than molecules with the sulfonate indirectly attached. The length of the backbone allows each sulfonate group to replace a sulfate in the lattice, thus binding the additive very strongly to the crystal surface, in a zipper-like manner, and inhibiting growth. For instance, 0.1 ppm of a polymaleic acid (polyvinyl sulfonic acid

at a pH of 3.8) decreases the growth rate of barium sulfate by nearly two orders of magnitude (depending on the supersaturation).

Waxes in diesel oil can crystallize at low temperatures. The crystals clog up the fuel filters in cars and prevent the motor from starting. To prevent this problem either wax crystallization should be prevented or only very small crystals should be allowed to form, which can pass through the fuel filter without any problem. As the former option is not very practical (it requires either removal of the waxes or storage of the fuel at higher temperatures) the only option is to add additives that block crystal growth. The design of an additive for such a purpose has been carried out using xylene containing n -C₃₂H₆₆ as a model fuel. A copolymer of fumarate vinyl acetate with different alkyl side chain lengths was used as an additive. The effective concentration at which the additive started to influence the growth of n -C₃₂H₆₆ was determined at a fixed supersaturation as a function of the alkyl side chain length. A clear relationship between the side chain length and the growth inhibition was shown, with a maximum effectiveness when the chain length was very close to the chain length of the solute. This shows that the structural match between the additive and the solute is critical for the effectiveness of the additive.

α -Lactose, a milk sugar, is a disaccharide containing a galactose and a glucose ring. Under influence of an acid, the α -glucose ring can be opened and closed again either in the α or the β form. In the latter form it is a tailor-made additive. The galactose moiety resembles lactose, but the different position of the hydroxyl group (β instead of α) hinders subsequent growth. The ' α -side' of the crystal can therefore be poisoned so the β -lactose molecules cannot attach to the crystal, and only one side is blocked. This results in the typical tomahawk shape of the crystals (Figure 8).

Figure 8 The α -lactose hydrate crystal grown in the presence of β -lactose. The (0 1 0) surface on the right is blocked because β -lactose can adsorb on the surface, causing a blocking impurity as shown in Figure 6C, while on the left the (0 $\bar{1}$ 0) surface is not blocked because the β -lactose can not adsorb on the surface.

A substance that is capable of crystallizing into structurally different but chemically identical crystalline forms exhibits polymorphism. A very common compound that can form polymorphs is water. Under atmospheric pressure and slightly below 0°C ice is formed with a density lower than that of water, so the ice floats on the water. Under higher pressure the ice can crystallize into polymorphs with higher densities that sink. Different polymorphs crystallize under different conditions. However, these conditions may be almost equal for rather complex organic compounds such as pharmaceuticals. In the pharmaceutical industry a strong desire exists to control the crystallization of polymorphs for a number of reasons. The polymorphic form of a pharmaceutical influences its effect and its lethal dosage. The crystallization processes of particular polymorphs are therefore protected by patents.

One way of controlling the crystallization of the correct polymorph is by means of template-directed nucleation of the polymorph. The template mimics a crystal face of the desired polymorph and nuclei of that polymorph can form onto the template. Up to now attention has mainly focused on templates consisting of Langmuir–Blodgett (LB) layers.

Calcite and vaterite are polymorphs of the compound calcium carbonate (calcite is the polymorph that forms under ambient conditions). Stearic acid spreads at the air–water interface, which when compressed as a LB monolayer is highly structured. When the acid group is ionized at higher pH the monolayer surface facing the solution consists of carboxylates that can bind calcium ions from the solution. At higher calcium concentrations calcite grows from the (1 $\bar{1}$ 0) face under the monolayer, while at lower calcium concentrations vaterite grows from the (0 0 1) face under the monolayer. It is suggested that the surface concentration of calcium under the monolayer is important: at high concentrations the calcium ions bonded to the monolayer mimic the (1 $\bar{1}$ 0) face of calcite while at lower concentrations they mimic the (0 0 1) face of vaterite, which is less densely packed with calcium ions. Many examples of template-induced growth are found in nature, as mentioned before and only recently has this technique for controlling polymorphs been exploited.

Concluding Remarks

Additives can be used to improve the handling and quality of crystal products from an industrial crystallization process. The large number of effects that an additive can have on the handling and the quality

all come down to the interaction between the additive and the different crystal surfaces. A general method was given for the design of additives, which involves gaining knowledge of the morphologically important crystal surfaces and on the interaction between these surfaces and the additive.

Biomineralization

D. Volkmer, University of Bielefeld, Bielefeld, Germany

Copyright © 2000 Academic Press

Many organisms have developed sophisticated strategies to direct the growth of the inorganic constituents of their mineralized tissues. Active control mechanisms are effective at almost all levels of structural hierarchy, ranging from the nanoscopic regime – the nucleation of a crystallite at a specific site – up to the macroscopic regime, where the biophysical properties of the mineralized tissue have to be matched to a certain function.

Among the many open questions, one of the most challenging scientific problems is to gain insights into the molecular interactions that occur at the interface between the inorganic mineral and the macromolecular organic matrix. Biogenic crystals often express exceptional habits that are seemingly unrelated to the morphology of the same type of crystals when grown under equilibrium conditions. For the most widespread calcified tissues it is frequently assumed that a structurally rigid composite matrix consisting of fibrous proteins and thereon adsorbed acidic macromolecules acts as a supramolecular blueprint that templates nucleation of the inorganic phase. Subsequent crystal growth proceeds within a specialized compartment which encloses a suitable aqueous microenvironment. The particular composition of solutes, which often comprises a complex mixture of dissolved electrolytes and macromolecules, has a strong influence on the morphology of the crystals. In the course of mineral deposition, growth modifiers may interact with the maturing crystal in different ways: dissolved macromolecules may be adsorbed onto specific crystal faces, thus slowing down or inhibiting deposition rates along certain crystallographic directions. Adsorbed macromolecules may be completely overgrown by the mineral to produce lattice defects or to introduce discontinuities in the crystal texture.

Efforts in trying to separate and mimic aspects of these complex interactions with simple model systems will help to improve our understanding of crystallization processes that are under biological control.

A profitable knowledge transfer in the direction of biologically inspired design strategies for building new and improved composite materials can be predicted for the near future.

The following account of biomineralization focuses on two special topics of this wide research field, namely ferritin and mollusc shell mineralization, which are considered here as illustrative examples. For a more comprehensive survey which includes further important types of biominerals (e.g. bone or biogenic structures made of amorphous silica) the reader should consider one of the many excellent monographs and review articles on the subject.

Ferritin: From Iron Storage to Nanoparticle Synthesis

Mineral deposition in the iron storage protein (ferritin) may be regarded as an archetypal biological model for the formation of a nanocrystalline mineral phase within a confined space. The structure and function of ferritin have been reviewed in great detail. Ferritin consists of an oligomeric protein shell (apoferritin) and a core of poorly crystalline Fe(III) oxyhydroxide (presumably ferrihydrite, $5 \text{ Fe}_2\text{O}_3 \cdot 9 \text{ H}_2\text{O}$). Iron is temporarily stored within and released from the central cavity of the encapsulating protein shell. The availability of several high resolution three-dimensional structures of apoferritins originating from different organisms provides a reliable basis to discuss possible pathways of iron biomineralization. Current biomimetic strategies to achieve similar properties include mineralization in oil-water microemulsions, block copolymer micelles, or biotechnologically produced capsule-forming proteins.

Apoferritin Structure and Biological Function

Apoferritins with different amino acid compositions have been isolated from eukaryotes as well as

Table 1 Characteristics of ferritins

<i>Iron storage protein</i>	<i>Source</i>	<i>Composition</i>	<i>Physiological functions</i>
Ferritins	Vertebrates Invertebrates	24-mer, predominantly heteropolymeric composed of H-, L- and M-chains Core of crystalline ferrihydrite (polydisperse) Fe/P ratio $\geq 10 : 1$, 1000–3000 Fe(III)/core	Mobile iron storage Iron detoxification Prevention from hydroxyl radical formation
Bacterioferritins	Eubacteria Fungi	24-mer, predominantly homopolymeric Up to 12 haem (cytochrome b_{557}) groups Core of amorphous hydrous ferric phosphate Fe/P ratio 1.1 : 1–1.9 : 1, 600–2300 Fe(III)/core	Precursor to magnetite in magnetotactic bacteria

Adapted with permission from Le Brun N, Thomson AJ and Moore GR (1997) Metal centres of bacterioferritins or non haem-iron-containing cytochromes b_{557} . *Structure and Bonding* 88: 103–138

prokaryotes (Table 1). Sequence similarities of haem-free ferritins and haem-containing bacterioferritins may fall below 20%. However, their quaternary protein structures are almost identical, suggesting that a convergent molecular evolution within different groups of organisms has independently led to an optimal solution for the availability of a mobile temporary iron storage.

While the general physiological effect of ferritin originating from different organisms may differ, it clearly functions as an iron deposit on the molecular scale, owing to several remarkable features:

- the apoferritin creates a confined space which ultimately restricts the maximum size of the inwardly growing mineral phase;
- several anionic residues induce a net negative charge on the inner protein surface which compensates for the positive surface charges of initially formed polycationic Fe(III) oxyhydroxy species;
- the H-chain ferritin subunit contains a ferroxidase centre that catalyses the oxidation of Fe(II) by molecular oxygen to yield Fe(III);
- the L-chain ferritin subunit bears glutamic acid residues in close proximity which point towards the central cavity, thus possibly acting as an active site for crystal nucleation;
- the apoferritin supports long range electron transfer across the protein coat, enabling fast reductive release of Fe(II) ions from the highly insoluble Fe(III) oxyhydroxide mineral.

Apoferritin is built up by 24 structurally complementary subunits that self-assemble to form a hollow shell of an approximate outer diameter of 11 nm. An individual subunit consists of a long 4- α -helix bundle with an additional short α -helix lying at an angle of about 60° to the bundle axis at the C-terminal side of the amino acid chain (Figure 1A). At the beginning of apoferritin self-assembly dimers form mainly through a multitude of hydrophobic

contacts along the juxtaposed 4- α -helix bundles. The complete apoferritin shell is composed of 12 dimers that form the faces of an imaginary rhombic dodecahedron (Figure 1B). The protein shell encloses

Figure 1 (A) Single apoferritin subunit; α -helix regions of the secondary protein structure are represented as cylinders. The arrow marks a putative mineral nucleation site (here: Glu 57, 60, 61 and 64 of L-chain horse apoferritin, PDB code: 1AEW). (B) Supramolecular architecture of the apoferritin protein shell: 12 subunit dimers form the faces of an imaginary rhombic dodecahedron. (C, D) View along the three-fold channels (the four-fold channels, respectively) of the apoferritin structure. Adapted from Harrison and Arosio (1996).

a nearly spherical cavity of an approximate diameter of 8 nm. The central cavity is accessible through channels of three-fold and four-fold symmetry which are situated at the vertices of the rhombic dodecahedron (Figure 1C, D). While the three-fold channels possess a hydrophilic surface, the four-fold channels are more hydrophobic in nature. The transport characteristics of the ferritin channels are still a matter of controversy. The three-fold channels are likely to be involved in the uptake and release of iron ions as well as in the regulation of the ferritin water content. For the four-fold channels an active role in the uptake of dioxygen has been proposed.

Ferritin Biomineralization

Since ferritin subunits spontaneously self-assemble *in vivo* as well as *in vitro* to yield the complete apoferritin shell, it has been possible to study mineral deposition within the ferritin cavity under various experimental conditions.

Mineral formation within the ferritin cavity proceeds via two different pathways (Figure 2): At low iron content, hydrated Fe(II) ions are taken up from the external medium by the H-chain ferroxidase centre where rapid oxidation takes place. Hydrated Fe(III) ions are released from the ferroxidase centre to

Figure 2 Iron mineral formation in ferritin. A self-assembled heteropolymeric shell forms a spatially confined mineralization compartment composed of H- and L-chain subunits that possess different roles in mineralization. The H-chain contains a pre-organized arrangement of coordinating amino acid residues (ferroxidase centre) which is able to take up two Fe(II) ions and to catalyse their oxidation to Fe(III) ions. The L-chain possesses four highly conserved glutamic acid residues, that are assumed to play a decisive role in Fe(III) mineral nucleation.

enter the ferritin cavity (path A). The inner apoferritin surface bears a multitude of primarily hydrophilic and anionic amino acid residues which point towards the central cavity. In particular, each L-chain subunit contains a distinct array of four potentially coordinating glutamate residues (Figure 1A) that could accumulate a small number of hydrated Fe(III) ions. The immobilized Fe(III) ions start to polymerize, leading to an OH⁻-bridged multinuclear Fe(III) oxyhydroxide cluster. Further cluster growth proceeds via addition of Fe(III) hexaqua cations to the cluster surface with concomitant loss of an H₂O ligand for each established coordinative bond.

On reaching a critical crystallite size, autocatalytic Fe(II) oxidation at the surface of the mineral nucleus outweighs ferroxidase-induced oxidation, and mineral growth continues until most of the cavity is filled by one (or several) Fe(III) oxyhydroxide nanocrystal(s) (path B). The pathways of iron transport into the cavity, as well as the primary product(s) of iron(II) oxidation, are not yet fully established.

Since hydrated Fe(III) ions form polycationic oligomers at the initial stages of polymerization, the general consensus is that L-chain glutamate residues contribute to a negative surface potential on the inside of the apoferritin shell in order to create a thermodynamic sink for Fe(III) oxyhydroxide deposition. In addition to this general effect, a more specific template effect on iron mineral formation has been proposed which takes into account the special arrangement of glutamate residues and the fact that the sequence motif is highly conserved among ferritins from different classes of organisms. The poor crystallinity of the ferritin mineral on the other hand, as well as the fact that nanosized Fe(III) oxyhydroxide particles spontaneously grow from Fe(III)-containing aqueous solutions, challenges this interpretation.

Ferritin Core Structure

The mineral phase of ferritin displays properties similar to the iron oxyhydroxide ferrhydrite which is widespread in nature. This mineral has been traditionally described as amorphous or colloidal ferric hydroxide – Fe(OH₃) – due to its poor X-ray diffracting properties. The actual composition however, is Fe₃HO₈ · 4 H₂O and recent X-ray absorption studies (Fe K-edge XANES and EXAFS spectroscopy) have shown that most of the Fe(III) ions are situated in identical, structurally well-defined coordination environments. A highly hydrated ferrhydrite slowly precipitates from Fe(III)-containing solutions at pH ≥ 2 at room temperature. The Fe(III) hexaqua cations

first oligomerize to yield chains of water-soluble poly-cations in which octahedrally coordinated Fe(III) ions are bridged by hydroxide anions. Further deprotonation and polymerization yield ferrihydrite, which, at close to its zero point of charge at pH 7–8, slowly and irreversibly dehydrates and rearranges to the thermodynamically more stable iron oxide hematite (α -Fe₂O₃). Although the details of the crystal structure and surface properties of ferrihydrite are still controversial, the current data support a structural model in which double chains of edge-sharing iron(III) octahedra are cross-linked via corners (Figure 2, top), similar to the essential structural elements of the mineral goethite (α -FeOOH). The dimensions of coherent X-ray scattering domains for synthetic ferrihydrite are within the range of 1–6 nm, which accounts for the characteristic broadening of X-ray diffraction lines. Temperature-dependent ⁵⁷Fe Mössbauer spectra of synthetic ferrihydrite and ferritin cores display identical features, indicating a superparamagnetic behaviour of the crystalline phase at room temperature and below. Therefore synthetic ferrihydrite precipitates, as well as ferritin cores, may be better described as nanocrystals rather than nanocolloids.

Biologically Inspired Nanoparticle Synthesis

The intriguing supramolecular architecture of ferritin, as well as its unique functional properties, might be taken as a model for the construction of artificial nanocompartments where crystal growth takes place within a spatially confined microenvironment under controlled conditions. Classical approaches that make use of the entrapped water content of oil–water microemulsions are likewise simple to carry out, but as a rule suffer from relatively broad size distributions of the precipitated nanoparticulate materials. For advanced applications, novel synthetic routes will therefore be required to control the dimensions of the desired inorganic nanoparticles. Examples of technologically important compounds which exhibit strongly size-dependent physical and chemical properties range from catalytically active, highly dispersed metal nanocolloids (e.g. Pt, Pd, Rh), quantum-confined semiconductor nanoparticles (CdS, CdSe) to nanoscale ferrimagnetic particles (e.g. γ -Fe₂O₃) and nanocomposite magnetic alloys. Recent examples of biologically inspired synthetic approaches to synthesize nanoscale inorganic materials include the use of biotechnologically engineered apoferritin shells and virus protein cages (capsids), or the use of monodisperse block copolymer micelles as nanoscale reaction compartments (see Further Reading).

From Calcified Tissues to Engineered Crystals

While ferritin represents an example of a nanosized crystalline biomineral, the architecture for example of a vertebrate bone or a mollusc shell spans several length scales. The morphology of the calcified tissue is ultimately encoded in the genome that governs the biosynthesis of required materials at the cellular level of structural hierarchy. Biomineralization therefore, as a highly complex phenomenon of living organisms, cannot be reduced to a single mechanistic aspect. The following representation of CaCO₃ mineralization in molluscs is admittedly a crude simplification which mainly concentrates on structural aspects, while at the same time ignoring the dynamic character of the entire process. Special emphasis here is put on induced CaCO₃ crystal nucleation, i.e. the early stages of crystal growth where the system properties can be described by supramolecular recognition events occurring at the mineral–matrix interface. At this level, common features of ferritin, mollusc shell or bone mineralization do exist: the interaction of highly specialized acidic macromolecules with different surfaces of the growing single crystal. Current research efforts focus on the isolation and characterization of macromolecules from calcified tissues. Functional properties of isolated macromolecules or fractions of macromolecules are systematically investigated for their ability to influence CaCO₃ nucleation, growth and polymorphism. Biologically inspired synthetic strategies try to assemble artificial matrices in order to mimic structural and functional properties of mineralizing tissues.

Crystallochemical Aspects of CaCO₃ Biomineralization

CaCO₃, together with amorphous silica, is the most abundant biomineral. There exist three CaCO₃ polymorphs – calcite, aragonite and vaterite – all of which occur in calcified tissues. A monohydrate (monohydrocalcite) and a hexahydrate form (ikaite) of CaCO₃ have been characterized as metastable precursor phases during the incipient stages of crystal formation (Table 2).

At ambient conditions, calcite is the thermodynamically most stable CaCO₃ polymorph. However, from oversaturated aqueous solutions containing Mg²⁺ at a molar ratio Mg/Ca > 4 (comparable to the composition of seawater), the only observed crystalline phase is aragonite, while at high supersaturation the metastable polymorph vaterite precipitates from solution.

Table 2 Characteristics of the most important CaCO_3 mineral phases

Mineral	Crystal system (space group)	Specific density (g cm^{-3})	Solubility ($-\log K_{sp}$)	Biological occurrence
Calcite (CaCO_3)	Trigonal ($R\bar{3}c$)	2.71	8.48	Very common
Aragonite (CaCO_3)	Orthorhombic ($Pmcn$)	2.93	8.34	Very common
Vaterite (CaCO_3)	Orthorhombic ($P6nm$)	2.54	7.91	Rare
Monohydrocalcite ($\text{CaCO}_3 \cdot \text{H}_2\text{O}$)	Trigonal ($P3_121$)	2.43	7.60	Very rare
Ikaite ($\text{CaCO}_3 \cdot 6\text{H}_2\text{O}$)	Monoclinic ($C2/c$)	1.77	7.12	Unknown

The arrangement of the ions in crystalline CaCO_3 may be described in terms of separate layers of cations and anions. Coordination environments for Ca^{2+} ions (CO_3^{2-} , respectively) in the polymorphs differ from each other, as a result of different successions of layers, as well as different crystallographic orientations of the planar carboxylate groups in the crystal lattices (Figure 3). In calcite, each single densely packed Ca^{2+} layer parallel to the ab plane is situated between single layers of CO_3^{2-} with each layer containing anions oriented in opposite directions. Each Ca^{2+} ion is situated in a distorted octahedral coordination environment of six different CO_3^{2-} anions. In aragonite, the positions of Ca^{2+} ions in the ab plane are nearly identical to those of the calcite structure. In contrast, the CO_3^{2-} anions below and above the Ca^{2+} layer are separated into two layers, which are lifted by 0.98 \AA along the c direction, leading altogether to a ninefold coordination of Ca^{2+} ions.

Shell Formation in Molluscs

It has long been recognized that calcifying organisms have developed active mechanisms to select the poly-

morph, and to control the distribution, shapes and orientations of crystals in their mineralized tissues. Molluscs are among the most thoroughly investigated organisms in this regard; they build concrete shells from CaCO_3 . The mollusc shell may be regarded as a microlaminate composite consisting of layers of highly oriented CaCO_3 crystals which are interspersed with thin sheets of an organic matrix. Crystals within separate shell layers usually consist of either pure aragonite or pure calcite. Vaterite, when present, is usually associated with shell repair. The succession of shell layers, as well as their pronounced ultrastructural features (see Table 3) are important characters in mollusc taxonomy. The main protective functions of the shell are to prevent desiccation, predation and abrasion. The shell also provides support for the body and a site for muscle attachment.

Shell formation occurs in two principal phases. The first involves the cellular processes of ion transport and organic matrix synthesis which occurs in different compartments of the molluscan mineralizing system (Figure 4A). The second phase comprises a series of crystal nucleation and growth processes taking place in a specialized mineralization compartment,

Figure 3 Ion-packing arrangement in the crystal structures of (A) calcite and (B) aragonite. The coordinative bonds between CO_3^{2-} anions (black sticks) and one of the Ca^{2+} ions (open circles) are emphasized with open lines. The minimum distances of Ca^{2+} ions in the ab planes for both crystal lattices are indicated at the bottom.

Table 3 Classification of mollusc shell layers

Shell layer	Composition	Ultrastructural characteristics	Function
Periostracum	Thin layer of hydrophobic sclerotized proteins (periostracin) 3,4-Dihydroxyphenylalanine (DOPA) Asp-rich proteins, chitin (occasionally)	Outer shell surface Little or no ultrastructural order	Space delineation Protection from corrosion Initial substrate for mineralization Camouflage/protective colouring
Prismatic layer	Calcite or aragonite Water-soluble Asp-rich glycoproteins	Outer shell layer extending inward from the periostracum Aggregates of uniformly oriented crystal prisms	$\text{Ca}^{2+}/\text{HCO}_3^-$ storage Multi-layered architecture
Nacreous layer	Aragonite β -Chitin fibrils, silk fibroin-like (Gly-, Ala-rich) framework proteins Water-soluble Asp-rich glycoproteins	Middle or inner shell layer Polygonal, laminar tablets arranged in broad, regularly formed, parallel sheets nearly parallel to the inner shell surface	creates more isotropic structural properties that strengthen the shell against mechanical loading (torsion, fracture)
Foliated layer	Calcite Water-soluble Asp-rich glycoproteins Water-soluble phosphoproteins	Lamellae of parallel and elongate blades of crystals dipping uniformly over large portions of the depositional surface

the so-called extrapallial space (Figure 4B). Crystals grow in intimate association with a secreted, highly specialized organic matrix. In order for crystals to form, the extrapallial fluid must become supersaturated with CaCO_3 , which imposes active accumulation strategies upon molluscs that inhabit a freshwater environment, where the external medium is depleted of Ca^{2+} ions. The concentration of Ca^{2+} ions is actively regulated by a Ca membrane transport system that is located in the body and the mantle epithelium. Active carbonate transport has also been postulated for the regulation of HCO_3^- ion concen-

tration. However, as an additional source of hydrogen carbonate, the mollusc may utilize metabolic carbon dioxide from its respiratory system. Any supply of HCO_3^- ions is tightly associated with carbonic anhydrase (CA) activity, an enzyme that catalyses the interconversion of carbon dioxide (CO_2) and carbonic acid (H_2CO_3). High carbonic anhydrase activity is detectable in the extrapallial fluid of molluscs, where the protein seems to be involved in removal of protons from the extrapallial fluid in order to maintain the pH within the appropriate range (7.4–8.3) for mineral formation.

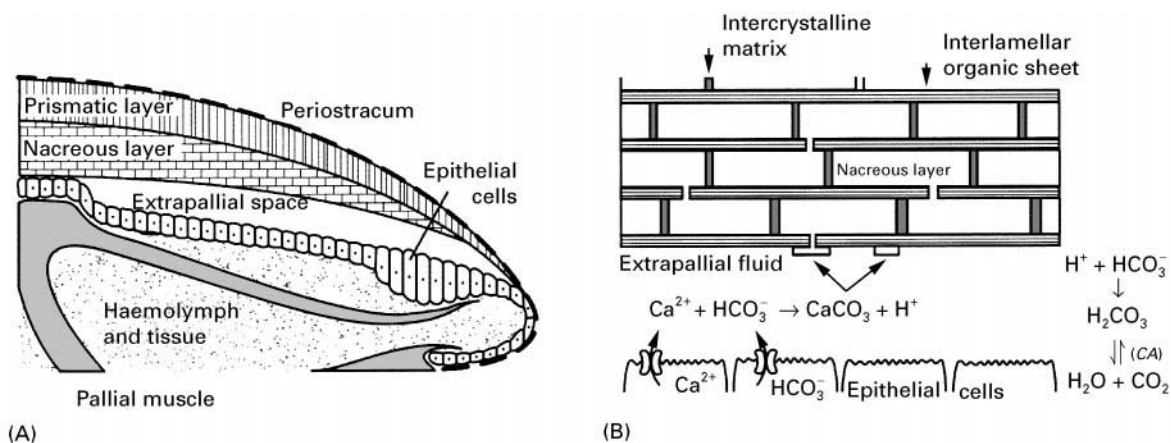

Figure 4 (A) Transverse section of the mantle edge of a bivalve showing the system of compartments. (B) Scheme of ion fluxes at the interface between the outer epithelial cells of the mollusc tissues and the incipient layer of nacre. (Simplified representations, not to scale.)

The extrapallial fluid also contains a complex mixture of inorganic and organic substances. Analysis of several species of marine and freshwater species showed that the major cations present are Na^+ , K^+ , Ca^{2+} and Mg^{2+} while the major anions are HCO_3^- , Cl^- and SO_4^{2-} . The organic components of the extrapallial fluid include amino acids, proteins, mucopolysaccharides and low molecular organic acids (e.g. succinic acid). The organic compounds are secreted by mantle epithelial cells, but their metabolic origins in mollusc tissue have not yet been located.

The Structure of Nacre

Biogenic crystals may use the inner surface of the periostracum, the surface of other, already formed crystals, or the organic matrix as a substrate. Special attention has been drawn to the microstructure of nacre which exhibits an exceptionally regular arrangement of tabular aragonite crystals. Thin interdigitated aragonite plates develop in close association with thin horizontally aligned organic layers (interlamellar sheets) upon which aragonite crystals are nucleated (Figure 4B, Figure 5). In order to grow crystals into a highly regular brickwork-like pattern, numerous nucleation events would have to be synchronized with each other at distant locations. An alternative growth mechanism was proposed to explain the precision by which aragonite platelets are uniformly co-aligned within the same and consecutive layers. According to this model, nacre may be constituted of extended, continuous single crystalline domains of aragonite platelets that are interconnecting by mineral bridges through the perforated interlamellar sheets.

Biologically Induced Crystal Nucleation

Putative Structure of Acidic Nucleation Sites in Calcified Tissues

One of the critical problems in understanding the mechanisms of matrix-associated mineralization is the lack of information on the three-dimensional structures of biological macromolecules that interface with the mineral. A literature search up to the middle of 1999 yielded very few examples where complete or partial information about the primary structure of macromolecules directly involved in mineralization have been determined (Table 4). Macromolecules isolated from mollusc tissues have traditionally been distinguished into two different classes, based on solubility properties. Chemical analysis showed that the insoluble fraction consists

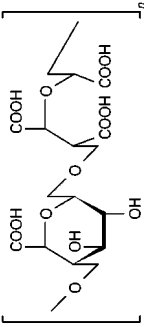

Figure 5 Fractured surface of the nacreous layer of the bivalve mollusc *Atrina rigida*. The inset shows the inner nacreous layer of tabular aragonite crystals (top) and the outer prismatic layer of columnar calcite crystals (bottom). SEM micrographs, scale bar denotes 1 μm . Courtesy of Y. Levi, Department of Structural Biology, Weizmann Institute of Science, Israel.

mainly of fibrous proteins (collagen, chitin) and/or polysaccharides. These macromolecules together build a rigid framework upon which specific macromolecules from the soluble fraction may become adsorbed. The primary function of the insoluble organic matrix is to subdivide the mineralization compartment into an organized network of microcompartments and thus to delimit the available space for crystal growth and/or to constrain the crystal packing arrangement to a certain extent. The surface of this macromolecular assembly may serve as a supramolecular template for oriented nucleation of single crystals, although this structure–function relation is difficult to prove for biological systems *in vivo*.

The macromolecules contained in the soluble fraction have sequence motifs in common which consist of repeating oligomeric units of acidic residues. Table 4 contains further representative examples of functional macromolecules from calcified tissues. However, the heterogeneity of sources/organisms for isolating these macromolecules, their different

chemical nature, and their association with different mineral phases clearly rule out a uniform function. They may roughly be divided into five different functional classes:

- concentration regulators: macromolecules that are linked to Ca^{2+} and/or CO_3^{2-} transport and metabolism (e.g. carbonic anhydrase)
- growth inhibitors: acidic macromolecules that strongly bind Ca^{2+} ions and become nonselectively adsorbed on to any arbitrary crystal face which is exposed to the mother liquor
- growth modifiers: acidic macromolecules that interact stereoselectivity with distinct faces of a nascent crystal
- texture modifiers: acidic macromolecules that become occluded and modify texture and mechanic properties of crystals
- nucleators: immobilized acidic macromolecules that form a highly regular template for induced crystal nucleation

Due to the complex nature of interactions in biological matrices, the same acidic macromolecule may belong to more than one of the above mentioned categories and its functional properties may change within different organisms and microenvironments.

To demonstrate a possible mode of molecular interaction between acidic macromolecules and crystal surfaces, this survey of mollusc mineralization will conclude with a brief section about induced CaCO_3 nucleation in biological systems. The body fluids of mineralizing organisms contain crystallization inhibitors that prevent spontaneously formed crystal nuclei from growing into larger crystals. To direct mineral deposition to the appropriate location, active nucleation sites have to exist in mineralizing compartments. The opening section about iron storage has already indicated how the molecular architecture of ferritins may be associated with nucleation of iron minerals. For induced calcite and aragonite nucleation, systematic investigations on biological and suitably assembled artificial systems have shed some light on the structural requirements of a putative nucleation site, especially in mollusc shells. The model of Addadi and Weiner proposes structurally pre-organized domains of acidic residues, that could serve as a supramolecular template for oriented crystal nucleation. Such highly ordered domains could result from acidic macromolecules being adsorbed on a rigid scaffold of insoluble matrix proteins (Figure 6). As an example, the interlamellar organic sheets of mollusc shell nacre consist of thin sheets of β -chitin (a water-insoluble (1 \rightarrow 4)-linked 2-acetamido-2-deoxy β -D-glucan) sandwiched between thicker sheets of silk fibroin-like proteins. Silk fibroin itself possesses microcrystalline

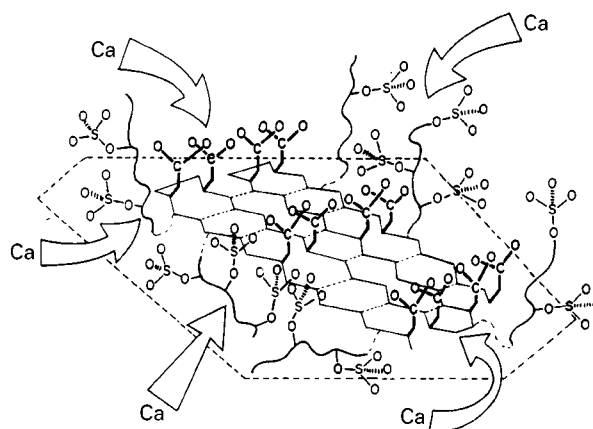

Figure 6 Schematic representation of a putative nucleation site in molluscan tissues. An acidic glycoprotein is anchored to a rigid substrate (as schematized by the broken lines) through hydrophobic or electrostatic interactions. The sulfate groups, linked to flexible oligosaccharide side chains, concentrate Ca^{2+} ions on an Asp-rich oligopeptide domain that is assumed to adapt a highly regular β -sheet conformation. A first layer of Ca ions may thus be fixed and oriented in space, upon which further mineral growth ensues. Reproduced with permission from Addadi and Weiner (1989).

domains of repeating $[\text{Gly-Ala-Gly-Ala-Gly-Ser}]_n$ units that adopt an antiparallel β -pleated sheet conformation. These domains have a highly regular and hydrophobic surface upon which acidic macromolecules are adsorbed from solution. In the course of adsorption, the acidic macromolecules has to fold into the appropriate conformation, in order to maximize its hydrophobic interactions with the silk fibroin surface. Possible candidates for acidic macromolecules interacting with silk fibroin in the described way are oligopeptides that include sequence motifs of $[\text{Asp-X}]_n$, ($\text{X} = \text{Gly}, \text{Ser}$), which have a strong tendency to fold into a β -sheet conformation in the presence of Ca^{2+} ions. As a consequence, the aspartic acid residues of $[\text{Asp-X}]_n$ sequences would be positioned at only one side of the β -pleated sheet, resulting in an organized two-dimensional array of carboxylate ligands.

It is tempting to assume that the carboxylate residues coordinate a first layer of Ca^{2+} ions which would in turn become the first layer of an epitaxially growing CaCO_3 crystal. However, a more profound analysis has so far failed to provide evidence for an epitaxial growth mechanism or a close stereochemical complementarity between the nucleating macromolecules and the incipient CaCO_3 crystal surface. Some properties of the mollusc shell ultrastructure rather point to less sophisticated nucleation strategies; examination of the common crystal orientations in a variety of calcifying organisms reveal that aragonite and calcite single crystals most frequently

nucleate from the *ab* planes. The arrangement of Ca^{2+} ions in this plane (the shortest distance between Ca^{2+} ions is 4.99 Å in calcite, and 4.69 Å in aragonite, respectively; Figure 3) is geometrically not commensurate with the period of amino acid residues in a protein β -strand (approx. 6.9 Å). Moreover, on pointing more or less perpendicular towards the Ca^{2+} ions in the crystal (0 0 1) face, the carboxylate residues of the β -pleated sheet cannot continue the parallel arrangement of planar carbonate anions in the underlying layer(s). The current nucleation model thus does not support the picture of a calcite or aragonite single crystal being nucleated from (0 0 1) crystal faces by virtue of stereochemical selection principles.

Despite the similar positioning of Ca^{2+} ions in the *ab* plane of calcite and aragonite, mollusc shells discriminate between the two polymorphs by secreting them separately in different layers (e.g. prismatic layer and nacre). This suggests that additional factors participate in nucleation. One possibility is that different Mg^{2+} concentrations in the fluids of aragonitic and calcitic layers may be present that could help to shift the balance between the two polymorphs. Another possibility is the presence of polymorph-specific macromolecules that interact with more than one face of the nascent crystal. For a valid explanation of selective nucleation of either polymorph, the current, essentially geometric model will have to be refined. A lot is expected from the first three-dimensional structure of a nucleating macromolecule, although its active conformation may depend on the accompanying insoluble organic matrix in the biological tissues. Finally, novel theoretical approaches are currently being investigated to explore realistic surface properties of the CaCO_3 polymorphs which consider surface relaxation as well as hydration of the outermost ionic layers.

Biologically Inspired Engineering of CaCO_3 Crystals

Several studies have been directed to the phenomenon of heteroepitaxy in CaCO_3 biomineralization. Seminal contributions have come from the group of Mann and co-workers who studied the influence of negatively charged surfactants on crystal nucleation. The group made use of a Langmuir film balance that allows for spreading surfactant molecules as a monolayer at the air–water interface with the charged head groups pointing toward the aqueous subphase. Nucleation of calcite single crystals was observed from monolayers of aliphatic monocarboxylic acids, sulfates or phosphonates. The crystals that grew

underneath the monolayers in general showed a significantly narrower size distribution and reduced nucleation time, as compared to calcite crystals precipitated spontaneously from supersaturated solutions. Moreover, the crystals grew crystallographically oriented relative to the monolayer. Calcite single crystals nucleated preferentially from the {10.0} face underneath compressed monolayers of amphiphilic carboxylic acids, while monolayers of alkylsulfates and -phosphonates led to calcite single crystals that nucleated from the (0 0 1) face. Detailed schemes were proposed to rationalize the different modes of interaction between the different head groups of amphiphiles in the monolayers and the corresponding faces from which the crystals were nucleated.

To gain more precise controls over the relative positions of coordinating residues, patterned self-assembled monolayers of bifunctional ω -terminated alkanethiols ($\text{HS}(\text{CH}_2)_n\text{X}$, $\text{X} = \text{CO}_2^-$, SO_3^- , PO_3^{2-} and OH) have been produced very recently on different supporting metals (Au, Ag) by means of microcontact printing. Depending on the appropriate combination of functional groups, length of alkyl chains, metal substrate and nucleating area, the selective nucleation of calcite single crystals has been achieved for a huge variety of crystallographic orientations. As a unique feature, the self-assembled monolayers allow one to grow isolated and oriented single crystals with a defined separation which is encoded in the tiling of the nucleating areas. The technique has been further employed to grow crystalline CaCO_3 layers that consist of alternating domains of differently oriented calcite single crystals.

The few cited examples demonstrate how model studies may focus on aspects of induced nucleation at organized organic surfaces. Single structural parameters of the organic matrix can be varied systematically and analysed for their influence on crystal nucleation and growth. Results gleaned from these experiments provide important informations that could help to interpret the observed, often highly complex, structures of biominerals. The models studied, furthermore, indicate as to how biologically inspired design and novel technical approaches combine into innovative synthetic strategies for engineering artificial crystalline architectures.

Control of Crystallizers and Dynamic Behaviour

Introduction

Ideally industrial crystallizers are operated in such a way that the product specifications are met under conditions that permit profitable, trouble-free production of the desired crystalline material. In industrial practice, however, many operational problems can be encountered that reduce the performance of the crystallizer. The most commonly encountered problems are listed here.

- Deposition of crystal solids on the crystallizer internals, often called scaling or fouling. This results in a reduction of the heat transfer in the heat exchanger or leads to plugging of the process lines and can even hamper the flow pattern and thus the mixing in the crystallizer.
- Alternate feed composition. The resulting changes in the level of supersaturation in the crystallizer can lead to nucleation bursts or depletion of secondary nuclei, having a severe effect on the dynamics of the process.
- Disturbances in the heat exchanger in the crystallizer. This leads to variation in the production yield and the crystal concentration, which in turn

affects the attrition and nucleation kinetics of the process.

- Inappropriate seeding procedures. In batch crystallization processes problems often occur when the amount or size distribution of the seeds crystals or the time of seeding is not optimal. This will result in a final crystal size distribution that is off specification.
- Temperature changes in the crystallizer. This can result in dissolution of the fine crystals in certain zones in the crystallizer, which can have a large impact on the crystallizer dynamics.
- Water injection due to rinse procedures after blockage in product, recycle or circulation lines. This can also result in a temporary decrease in the supersaturation, causing internal dissolution of the fine crystals.

In addition slow, low-order oscillations of the crystal size distribution (CSD) are often observed, which are caused by internal feedback mechanisms in the crystallization process and periodically give rise to an excessive number of fine particles in the product.

To avoid these operational problems, all relevant process variables affecting the crystallization process must be kept within the acceptable limits defined during the design of the process. Not all of the process variables need to be controlled dynamically. Some of them are controlled directly by the equipment design, and others are directly coupled to other variables. Some must be actively controlled to enforce the right process conditions, for instance the temperature profile during a batch cooling process. Others must be manipulated to compensate for the effect of process disturbances. Table 1 shows a list of the major pro-

cess variables for continuous and batch processes. There has been extensive discussion in the literature about the role of each of the process variables and how they are controlled in a variety of crystallizer configurations.

The major process variables in a crystallization process are the level of supersaturation of the solvent, the energy dissipation, the CSD and the distribution of these variables over the crystallizer. These process variables determine to a large extent the kinetic processes (such as nucleation growth and agglomeration) that dominate the crystallization process. They interact with other process variables in a complex way. The presence of interactions and internal feedback mechanisms in the crystallization process limits the success of simple feedback control schemes and favours the use of model-based multivariable controllers, which are able to anticipate these interactions. Unfortunately multivariable control studies for industrial crystallizer are rare and almost completely lack experimental verification.

Depending on the type and scale of the crystallizers, the contents will not be uniformly distributed. Profiles are normally present in the temperature, concentration and particle concentrations, especially around heat exchangers and in baffle and boiling zones. It has recently been shown that the presence of such profiles can have a strong impact on the crystallizer performance. In general these inhomogenities are acceptable as long as the process variables within these zones stay within the acceptable limits and are time-invariant. The main problem in this respect, however, is that the process models normally used for control design do not take account of the presence of these profiles. Compartmental modelling, which has been used to improve the design of industrial crystallizers, should also be applied to control design.

This article gives an overview of the new developments in the control of the CSD for both continuous and batch crystallizers. Attention is focused on the direct control of the CSD either by simple, single-input/single-output feedback control or by multivariable control, using techniques that have been experimentally verified. The reason for this limitation is that process models normally used in crystallization research have a bad reputation with respect to their prediction of the process behaviour. Different crystallizer configurations are analysed with respect to available process actuators. In addition the process models, which form the basis for the controller design and the choice of the measurement technique, are discussed. Some excellent review articles on this topic are used as the starting point of this overview.

Table 1 Process variables to be controlled in industrial crystallizers (after Rawlings *et al.*, 1995)

<i>Continuous operation</i>	<i>Batch operation</i>
Process temperature	(Rate of change in) process temperature
Heat flux to/from process	(Rate of change in) heat flux to/from process
Residence time of crystals	Batch time
Level (volume)	Level (FED batch)(volume)
Feed properties	
Concentration	
Temperature	
Flow rate	
Impurity level	
Slurry concentration	Slurry concentration
Purge flow	
Agitator and pump speed	Agitator and pump speed
CSD	CSD

Modelling of Industrial Crystallizers

The development of an advanced control strategy requires a dynamic model that accurately describes the behaviour of the process. The derivation of such a model implies identification of the model structure and estimation of the model parameters using experimental data, and verification of the model. Parameter estimation falls beyond the scope of this article and will not be covered here.

The modelling of industrial crystallizers is dominated by the presence of the so-called population balance, which describes the evolution in time of the CSD in the crystallizer. The population balance provides a generally accepted approach to the modelling of dispersed phase systems and allows specification of the product quality in terms of the CSD. The general form of the population balance equation (PBE) is as shown in eqn [1]:

$$\begin{aligned} \frac{\partial(n(L)V)}{\partial t} = & -V \frac{\partial(G_L(L)n(L))}{\partial L} + B(L)V - D(L)V \\ & + \sum_{j=1}^m \phi_{v,in,j} n_{in,j}(L) \\ & - \sum_{k=1}^n \phi_{v,out,k} h_{out,k}(L)n(L) \end{aligned} \quad [1]$$

where the amount and the size of the crystals (or particles) are expressed in terms of number density $n(L)$ and crystal length L . V is the suspension volume in the crystallizer, with m streams entering and n streams leaving the crystallizer at volumetric flow rates of ϕ_v . $G_L(L)$ is the linear size-dependent growth rate, and $B(L)$ and $D(L)$ are birth and death rates respectively. Birth and death events can be caused by agglomeration and by the birth of small crystals, called nuclei. The classification function $h(L)$ describes the relation between the CSD in the crystallizer and that in an outlet stream.

As the PBE is a partial differential equation with respect to time t and crystal length L , two boundary conditions are needed to solve it analytically:

$$n(0, t) = \frac{B_0}{G_L(0)} \quad [2]$$

$$n(L, 0) = \text{initial distribution} \quad [3]$$

As primary and secondary nucleation typically involves the birth of small crystals, nucleation is often presented as the birth of nuclei at zero size. Instead of a birth term in the PBE for the nucleation event $B(L)$ that happens over a size range $0 \leq L \leq \gamma$, the birth rate B_0 given by boundary eqn [2] is used. These two

are related as shown in eqn [4]:

$$B_0 = \int_0^\gamma B(L) dL \quad [4]$$

For the second boundary condition a seed population or a population formed by the outgrowth of primary nuclei can be substituted.

The mass balance is given by eqn [5]:

$$\begin{aligned} \frac{dM_{\text{total}}}{dt} = & \phi_{v,feed}(\varepsilon_{\text{feed}}\rho_{\text{feed,liquid}} + (1 - \varepsilon_{\text{feed}})\rho_{\text{crystal}}) \\ & - \phi_{v,product}(\varepsilon\rho_{\text{liquid}} + (1 - \varepsilon)\rho_{\text{crystal}}) \\ & - \phi_{v,vapour}\rho_{\text{vapour}} \end{aligned} \quad [5]$$

The component balances are given by:

$$\begin{aligned} \frac{dM_i}{dt} = & \phi_{v,feed}(\varepsilon_{\text{feed}}\rho_{\text{feed,liquid}}w_{\text{feed,liquid},i} \\ & + (1 - \varepsilon_{\text{feed}})\rho_{\text{crystal}}w_{\text{feed,crystal},i}) \\ & - \phi_{v,product}(\varepsilon\rho_{\text{liquid}}w_{\text{liquid},i} \\ & + (1 - \varepsilon)\rho_{\text{crystal}}w_{\text{crystal},i}) \end{aligned} \quad [6]$$

where $i = 1, \dots, N_{\text{comp}}$, and:

$$M_i = V(\varepsilon\rho_{\text{liquid}}w_{\text{liquid},i} + (1 - \varepsilon)\rho_{\text{crystal}}w_{\text{crystal},i}) \quad [7]$$

where component $i = 1$ is the main compound to be crystallized, and components $i = 2, 3, \dots, N_{\text{comp}}$ are the impurities present.

The distribution coefficients relate the impurity uptake by the solid and the concentration of the impurity in the liquid phase, as shown in eqn [8]

$$k_{\text{distr},i} = \frac{w_{\text{crystal},i}}{w_{\text{liquid},i}} \quad [8]$$

where $i = 2, \dots, N_{\text{comp}}$.

The enthalpy balance with the production rate or solids production P is given by eqn [9]:

$$\frac{dH}{dt} = \phi_{H,feed} - \phi_{H,product} - \phi_{H,vapour} + Q_{\text{heat}} + P\Delta H_{\text{cr}} \quad [9]$$

in which H denotes the enthalpy of the crystallizer content and ϕ_H the enthalpy of the particular stream. Q_{heat} is the effective heat input to the system including heat losses.

In order to complete the model, relations are needed for nucleation and growth. In many cases a size-independent growth rate is determined with a power law relation, as shown in eqn [10]:

$$G_L = k_g \sigma^g \quad [10]$$

where σ is the relative supersaturation. For the secondary nucleation a comparable function is used (eqn [11])

$$B_0 = k_N \sigma^b N^b M_T^j \quad [11]$$

in which N is the stirrer frequency and M_T is the total crystal mass in the crystallizer. Note that B_0 and not B is calculated with this relation. Although these functions are still used, especially in controller design studies, it has been shown that in reality the growth rate function is more complicated and size dependent. In addition, the power law for the nucleation given in eqn [11] is not suitable for describing the dynamics in secondary nucleation dominated crystallization systems and improved relations have proven to give a much better description of these kinetic processes. Here the relations are used because they have been applied in controller design studies. The growth rate is given by eqn [12]:

$$G_L(L) = p_6(C - C_s)^{p_7} \left(1 - \frac{L^{p_8}(L_e^{p_8} + L^{p_8})}{L_e^{p_8}(L^{p_8} + L_a^{p_8})} \right) \quad [12]$$

in which L is the crystal size. In this relation the growth rate decreases beyond a certain crystal size L_a due to attrition, while L_e is the maximum crystal size of the crystals. p_6 , p_7 and p_8 are model parameters, which have to be estimated. The relation for the secondary nucleation is shown in eqn [13]:

$$B_0 = p_3 \left[\int_{p_4}^{\infty} n(L, t) L^{p_5} dL \right]^{p_1} (C - C_s)^{p_3} \quad [13]$$

Here B_0 is calculated assuming that the nuclei have a negligible size. Note that only crystals beyond a certain size p_4 contribute to the secondary nucleation.

State Space Models

The design of model-based controllers requires a state space representation of the process model. As the population balance is a first-order nonlinear partial differential equation, a transformation must be used to get such a form.

Using the definitions of the moments of the distribution, the population balance can be transformed into a set of moment equations (eqn [14]):

$$m_j = \int_0^{\infty} n(L) L^j dL \quad [14]$$

For a continuously operated system with no impurities, a constant V , a size-independent growth rate, no agglomeration, nucleation at zero size, one crystal-free inlet stream, and a nonclassified product stream,

the population balance (eqn [1]) simplifies into eqn [15]:

$$\frac{\partial n(L)}{\partial t} = -G_L \frac{\partial n(L)}{\partial L} - \frac{n(L)}{\tau} \quad [15]$$

with similar boundary conditions. This equation can be reduced to a set of ordinary differential equations using the moment transformation (eqn [16]):

$$\frac{dm_j}{dt} = jG_L m_{j-1} - \frac{m_j}{\tau} + B_0 L_0^j \quad [16]$$

The first four moment equations, together with the kinetic relation (eqns [10] and [11]) and the mass, energy and component balances, form a closed set which describes the crystallization process. Unfortunately, the description will not be very realistic because of the large simplifications which form the basis of this description.

Other methods have been used to obtain a state space model. First of all the method of lines is applied to solve the population balance yielding a state space representation. For controller design this high order nonlinear model was first linearized and then further reduced. As an alternative a black box model was derived using system identification techniques.

Crystallizer Configurations

For continuous crystallization processes several types of crystallizer have been developed, which are used for different applications. The most common types of crystallizers are listed here.

- Forced circulation crystallizer (see Figure 1A). The most widely used crystallizer. It is often treated as a well mixed crystallizer, although several studies have shown that large variations in supersaturation exist within the crystallizer volume. Therefore crystal growth is limited to a small part of the crystallizer (in the vicinity of the boiling zone), and depending on the temperature rise in the external heat exchanger, even dissolution of the fine crystals will take place in that part of the crystallizer. Actuators to control the crystal size distribution are limited although configurations exist with an elutriation leg in which selective removal takes place. The level of supersaturation can be affected by control of the evaporation rate, while the profile can be influenced by adapting the circulation flow rate through the external heat exchanger. The main operational problems encountered with this type of crystallizer are scaling in the boiling zone or in the heat exchanger.

Figure 1 (A) Forced circulation and (B) stirred draft tube baffle (DTB) crystallizer with an external heat exchanger and fines destruction. Both crystallizers are produced by USFilter's HPD.

- Draft tube baffled (DTB) crystallizer (see Figure 1B). This crystallizer enables the generation of larger crystals using fines removal, which is done by installing a skirt baffle to create a settling or annular zone. The flow in the draft tube thus has to be upwards, which is effected by the impeller that also creates most of the attrition fragments. The fines flow can be diluted or heated to partly or totally dissolve the fines. An increase in the fines removal flow increases the number of fines that are removed from the crystallizer, but also increases the cut size of the fines. The fines loop in this way serves as an actuator that can be applied for control of the mean crystal size, although the variation in mean crystal size that can be achieved is limited. The elutriation leg, when present, serves more as a washing device to remove the impurities from the crystal than as a product classifier. The DTB crystallizer is among the best-studied crystallizers, because of the low order oscillations which are often observed. Other operational problems are scaling in the boiling and baffle zones.
- Fluidized-bed crystallizer (see Figure 2A). This crystallizer is especially designed to produce large and uniformly sized crystals. At the top of the bed the crystals are settled, and only the fines leave the crystallizer with the exhausted mother liquor to be circulated through the heat exchanger after mixing with the feed stream. The hot circulated flow enters the vaporizer head, where the solvent is flashed off.

The supersaturated solution leaves the vaporizer through the downcomer, and enters the densely packed fluidized bed at the bottom of the crystallizer. The supersaturation is consumed on its way up, and a coarse product leaves the crystallizer at the bottom. The main control problems are stabilizing the fluidized bed and keeping the supersaturation in the circulation loop, and specifically in the boiling zone and the downcomer, within certain limits to prevent spontaneous (primary) nucleation. Also low-order cycling occurs in this type of crystallizer, which is however much less well studied than the DTB crystallizer. Although fines dissolution already takes place in the circulation loop, a separate fines removal loop can be installed to control the CSD in the crystallizer. In addition a clear liquor overflow stream is sometimes used to control the slurry density in the fluidizer (double draw off).

- Cooling crystallizer (see Figure 2B). In this crystallizer the slurry is circulated through a heat exchanger. For crystallization from solution the slurry is pumped through a tube and shell heat exchanger, with a ΔT range between the tube and the wall of 5–10°C. The temperature decrease in the heat exchanger must be controlled precisely.

As can be seen from these descriptions, the number of available process inputs to manipulate the CSD in the crystallizer is rather limited. The actuator most used

Figure 2 (A) Fluidized bed crystallizer from USFilter's HPD and (B) cooling crystallizers from Swenson.

in control studies is the fines dissolution flow rate, although in industrial crystallizers this flow cannot be manipulated freely. It is constrained on the lower side by the heat input of the system and by the maximum temperature increase of the fines flow. Selective product removal using an external product classifier such as a wet screen or a hydrocyclone seems to be an attractive additional process actuator method, which can be implemented irrespective of the crystallizer used.

Measurements

The on-line measurement of the relevant process variables forms an essential and often difficult part of the control strategy. For the CSD control the most relevant process variables are the supersaturation and one of the characteristics of the CSD. The main measurement techniques are summarized next.

- **Supersaturation.** Except for some crystallization systems (sugars) the direct measurement of supersaturation is either impossible or not accurate enough for control purposes. Recently however several studies have shown that it is possible to measure the supersaturation on-line in a crystallizer using attenuated total reflection (ATR) probes in combination with Fourier transform infrared (FTIR) devices. Successful applications of density measurements have also been reported.
- **On-line CSD measurement.** A number of commercial instruments are available nowadays to determine CSD of crystal slurries. Of these the laser diffraction instruments have been shown to give a reliable measurement in diluted suspensions (at particle concentrations below 1 vol%). A major

drawback to the use of these instruments in a process is the need for an on-line dilution system to dilute the crystal suspension. A more recently developed instrument, measuring the attenuation of planar ultrasonic waves, forms an interesting alternative, because suspensions up to a concentration of 30% (by volume) can be measured without dilution.

- **In-line CSD measurement.** In-line sensors measuring the reflection of laser light and analysing the back-scatter peaks or images enable the analysis of some properties of the CSD inside the crystallizer, which can be of value for control of crystallizers. The main difficulty with the use of these probes is in identification of the relation between the information from the sensor and a process variable which is relevant for the control of the process.
- **Obscuration measurement.** The obscuration is defined as the fraction of light that is obscured by the crystals present in a flow cell and is a measure of the second moment of the distribution. As with laser diffraction this relation is only valid when multiple scattering can be avoided, i.e. at low particle concentrations. Obscuration measurements have been used to measure the number of fines crystals present in the fines removal loop.
- **Particle counter.** An optical particle counter measures the number of particles in a predefined size window in the crystallizer simply by counting the number of pulses from a light detector that are caused by the passage of the particles through a laser beam. The size window is defined as a result of the classification function of the funnel used to withdraw the process liquid from the crystallizer and the detection threshold of the detector, which can be adapted. This counter, which has been

successfully used to control a DTB crystallizer on a pilot-plant scale, forms an attractive alternative to the expensive CSD measurement devices.

The choice of the signal used by the controller, as well as the choice of the instrument, can be decisive for the performance of the controller. Using a CSD measurement, different characteristics of the CSD can be chosen. Analysis of different possibilities suggests that a reduced signal based on a principle component analysis of the raw diffraction data of a Malvern laser diffraction instrument, y_r , gave the best controller behaviour. The median crystal size, however, does not appear to be a suitable signal for control of the CSD, because of large delays in the response and its low sensitivity for changes in the small crystal area.

Control of Continuous Crystallizers

Crystallization Dynamics

As indicated in the introduction, problems in the operation of continuous crystallization processes can lead to large disturbances in the dynamics of an industrial crystallizer. In addition, slow oscillations in the CSD may occur, which do not seem to be caused by process disturbances, but are an intrinsic property for certain process configurations and are related to the internal feedback mechanisms which are present

in the crystallization process. This so-called slow cyclic behaviour is only seen in DTB and fluidized bed types of crystallizer configurations in the presence of fines dissolution and/or classified product removal. Figure 3 shows an example of this behaviour for a 1000 L evaporative DTB crystallizer. For higher values of the fines removal flow rate a limit cycle was reached in the median crystal size, during which the median crystal size varied between 240 and 1040 μm in cycles of about 5–6 h. Oscillatory behaviour has also been reported after selective product removal.

The stability of an open loop continuous crystallizer has been the subject of many studies. The techniques used involve the Laplace transformation of the linearized version of the population balance or conversion to a set of ordinary differential equations using the moment transformation. These solution methods, however, pose severe limitations on the models.

Based on a stability analysis, two types of unstable behaviour, have been identified, namely low order and high order cycling. High order cycling can be caused by very high orders in the power law equation for the nucleation kinetics, which seems unlikely for most crystallization systems. Low order cycling on the other hand can be caused by nonrepresentative product removal.

In more recent work it has been established that simple power law kinetics are unable to explain the

Figure 3 Experimental time response in a DTB crystallizer at start-up of the median crystal size for different fines removal flows (θ_f) and thus different residence times for the fines (r_f). Eek *et al.*, 1995b.

dynamic behaviour in industrial DTB crystallizers. Nucleation models that only take into account crystals beyond a certain minimum crystal size have been shown to give a much better description of the crystallization kinetics.

Some of these limitations in the stability analysis have been removed by using modern analytical techniques, which are based on the reduction of the system of balance and kinetic equations into one single integro-differential implicit equation. The steady state solution of this equation and that of the linearized equation around that point enables an analysis of more complex crystallization models.

Feedback Control

Experimental studies of feedback control schemes for laboratory and bench scale crystallizers have been based on the measurement of the suspension density in the fines removal line by manipulating the fines removal flow. The major drawback of this method is that the manipulation of the fines stream influences not only the number of crystals in the fines flow but also the cut-size of the baffle zone. Therefore the controller will in essence control the fines density removed from the system and not the fines density in the crystallizer.

An in-line Lasentec probe has been used to control a 1000 L DTB crystallizer producing potassium chloride using the fines removal flow as a process actuator. Problems identifying the optimal signal from the sensor and process disturbances affecting the CSD measurements decreased the efficiency of the controller.

The most complete study was one in which the fines removal rate was used as the process actuator to control the process. Figure 4 shows the general control scheme in which u is the process input on which the controller acts, in this case the fines removal rate t and y the process output. d and m are possible process disturbances and the measurement noise respectively.

An on-line particle counter, measuring the number of crystals in a predefined size range (60–100 μm), was used. The control equation is then shown in eqn [17]:

$$Q_f = k_p \left(\varepsilon_n + \frac{T}{T_i} \sum_{n=0}^k \varepsilon_k \right) \quad [17]$$

$$\varepsilon_n = N_f - N_{f,\text{setpoint}}$$

The error ε_k is the difference between the counter output and the set-point value. T is the sample time and T_i the integral or reset time. The following functions of the controller were tested.

Figure 4 Feedback single-input/single-output control scheme.

1. Stabilization of the process. A considerable reduction in the oscillations after start-up was obtained in closed loop compared with the open loop behaviour (see Figure 5). The severe oscillations resulting from the onset of a product classifier (wet screen) could also be suppressed by the controller (see Figure 6).
2. Set-point tracking. The set-point in the number of fines could be followed by the controller. The changes in the set-point for the number of fines also resulted in changes in the median crystal size of the crystal produced.
3. Disturbance suppression. A process disturbance introduced in the process by closing the product flow for 1 h was analysed. It was shown that open loop response on the disturbance was almost completely suppressed in closed loop operation of the process (see Figure 7).

The choice of the size range for the particle counter, which could be affected by the detector threshold and the settling velocity in the funnel used to discharge the particles from the crystallizer, is essential for the performance of the controller. It has been shown that when the detection size range is moved to particles below 40 μm the controller becomes unstable.

As an alternative to the particle counter, the reduced signal of the laser diffraction instrument was used. Similar results were obtained (see Figure 6).

Figure 5 (A) Open and (B) closed loop start up trend of the median crystal size. (Eek, 1995)

Figure 6 Open and closed loop trends in the y_1 , the x_{50} and the total crystal mass after the onset of a product classifier at a. Points b, c and d represent changes in controller set point and product flow rate respectively. (Eek, 1995.)

Multivariable Control

Only a limited number of multivariable control studies is available and only one of them has been tested experimentally. A state space model must be the basis

for a multivariable control design:

$$\begin{aligned}\dot{x} &= A(t)x(t) + B(t)u(t) \\ y &= C(t)x(t) + D(t)u(t)\end{aligned}\quad [18]$$

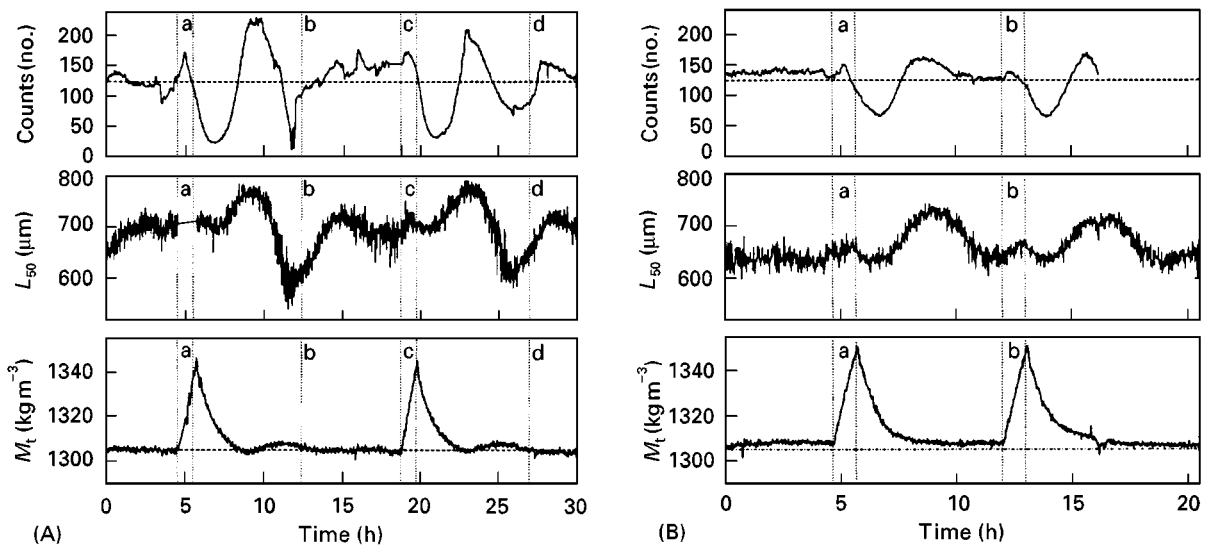

Figure 7 Measured (A) open and (B) closed loop responses of the counter signal, the median crystal size and the product magna density due to a disturbance in the product flow at a and c for the open loop experiment and at a and b for the closed loop experiment (Eek, 1995).

x is the vector of state variables. The crystallizer model must therefore be transformed into a state space representation. This can be achieved by the moment transformation, which is however only valid for a mixed suspension mixed product removal (MSMPR) type of crystallizer with simple crystallization kinetics. Application of the method of lines also yields a state space representation of the model.

An important topic in the design of a multivariable controller is the choice of the input–output pairs. On the basis of a relative gain array analysis with experiments done on a 1 m³ KCl crystallizer, a control structure with the fines, the product and the feed flow rate as process inputs, and the mean crystal size, the weight percentage of solids and the supersaturation as process outputs has been proposed.

On the basis of a controllability analysis the median crystal size has been rejected as an output variable because of the long delays. The control structure shown in Figure 8 was proposed as an alternative. This control structure was experimentally analysed on the 1000 L evaporative DTB crystallizer using a model predictive controller in combination with a state estimator. The controller was based on a linearized first principle model using the method of lines to transform the model into a state space representation. The controller showed good performance with respect to stabilization, disturbance rejection and set-point tracking, which was slightly better than that of a multiloop PI controller. This improvement is related to the interaction, which is taken into account in a multivariable model predictive control (MPC) controller, and the better constraint handling of this controller.

Control of Batch Crystallizers

Batch crystallizers are used extensively for crystallization procedures that are of small capacity and have a high added value, and often when multipurpose reactors are used for the crystallization process. Therefore the control of a batch process differs considerably from that of a continuous process. In addition, although a batch crystallizer can be described by a similar model to the continuously operated crystallizer, because of the inherently nonstationary process conditions and the strong dominant role of the start-

Figure 8 Input–output structure for a multivariable controller (Eek, 1995).

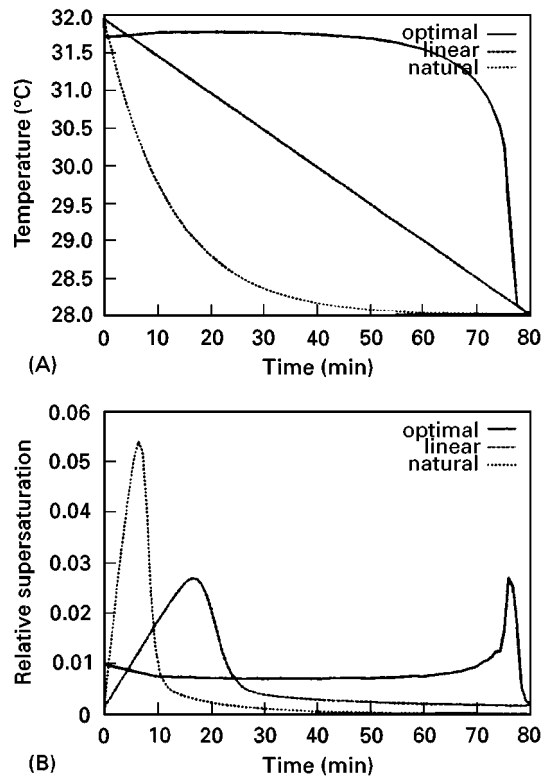

Figure 9 (A) Temperature profiles for a batch cooling KNO₃–H₂O crystallizer and (B) the resulting supersaturation in the crystallizer for different cooling policies (Miller and Rawlings, 1994).

up phase on the product quality process conditions, a completely different control strategy must be followed.

Literature references to the control of batch crystallization processes are mainly directed towards finding cooling or supersaturation profiles (a supersaturation versus time trajectory) that optimizes the product quality of the crystals profile.

Cooling profiles have been determined directly from MSMPR crystallization models with some additional simplifications. Other studies use simulation to calculate a cooling profile that maintains a constant supersaturation or an optimal control theory in combination with an objective function for the final product. The problem with these studies is that they all are limited to strict crystallizer configuration (MSMPR, no fines removal), and simple kinetic models. In addition they are unable to incorporate constraints in the process variables.

An alternative approach is to solve the general multivariable optimal control problem as a nonlinear programming problem.

Using this approach an optimal cooling programme can be calculated. An example is shown in Figure 9, in which a natural, a linear and an optimal

cooling profile are given together with the resulting supersaturation profile for a $\text{KNO}_3\text{-H}_2\text{O}$ system crystallized in a 3 L cooling crystallizer. The curves were determined using a first principle model in which four parameters were estimated using experimental data, maximizing the terminal seed size. Constraints were imposed on the crystallizer temperature and on the production yield. Experimental verification of the optimal cooling profile gave a 9% increase in the terminal seed size over that with linear cooling, and an 18% increase over that with natural cooling.

The determination of optimal cooling profiles is, however, not sufficient for an optimal operation of a batch crystallizer. Uncertainties in the start-up phase and in the crystallization model make the need for on-line measurements and a feedback control relevant. Depending on the reproducibility of the start-up phase, on line optimization procedures might be desirable for optimization of the process.

Conclusions

The control of both continuous and batch crystallizers has been shown to be feasible and can result in a considerable improvement of the process performance. Impressive results have been obtained even with a simple feedback controller, especially in the suppression of the process disturbances and in the stabilization of the process. This makes the application of this CSD control likely in industry in the near future. This progress is based on an extensive analysis of the crystallization process (including the derivation of a reliable process model), the available measurement techniques and the process actuators. On the other hand, because of limitations in the process actuators and the internal feedback loops in the crystallization process, variations in the product specifications (such as the median crystal size) were very limited, especially in continuous crystallization. The situation can only be improved by better crystallizer designs.

It has been shown that there are process models available, that can give a reasonable description of process behaviour. These models are however very empirical in nature and are in principle input-output models. They lack a fundamental description of the underlying (local) phenomena, which is needed to predict the influence of scale, geometry and the physical/chemical properties of the crystallization system. Only then we will be able to design crystallizers and control systems without the need for an extensive research programme.

A better understanding and description of the local crystallization phenomena may also be the key for the

improvement of the multivariable controllers by a better description of the interactions. Results have shown that there is no incentive for a multivariable controller, because the simple feedback controller gives comparable results with much less effort.

Symbols Used

b, g, h, j	Kinetic parameters
B_0	Birth rate ($\text{no. m}^{-3} \text{s}^{-1}$)
$B(L)$	Birth rate (size based) ($\text{no. m}^{-3} \text{m}^{-1} \text{s}^{-1}$)
C	Concentration (kg m^{-3})
C_p	Specific heat ($\text{J kg}^{-1} \text{K}^{-1}$)
C_s	saturation concentration (kg m^{-3})
$D(L, t)$	Death rate ($\text{no. m}^{-3} \text{m}^{-1} \text{s}^{-1}$)
G_L or G	Linear growth rate (m s^{-1})
H	Enthalpy
H_{cr}	crystallization enthalpy (J kg^{-1})
$h(L)$	Classification function (-)
K_N	Nucleation rate constant (-)
k_{distr}	Distribution constant impurity uptake (-)
k_g	Growth rate constant (m s^{-1})
L	Particle length [m]
m_j	j th moment of a distribution (-)
M_T	Total crystal mass per unit crystallizer volume (kg m^{-3})
N_{comp}	No of components (-)
$n(L)$	Number density ($\text{no. m}^{-3} \text{m}^{-1}$)
P	Production rate (kg s^{-1})
$p_1 \dots p_9$	kinetic parameters
t	time (s)
u	process input
V	Crystallizer volume (m^3)
y	process output
y_r	control signal derived from measured light diffraction pattern of the product crystals
w	Mass fraction (-)
ϕ_v	Volumetric flow rates ($\text{m}^3 \text{s}^{-1}$)
ε	Fraction free liquor (-)
ρ	Material density (kg m^{-3})
σ	Relative supersaturation (-)
τ	Residence time (s)

Magmas are hot (eruption temperatures range between 600°C and 1400°C), multicomponent, but generally silicate-dominated melt systems formed by processes of partial melting in the interior of the earth. Silicon and oxygen are the major constituents of most magmatic systems, apart from those of the carbonatite association, where NaCO₃ and CaCO₃ are significant components. This article considers crystallization in silicate-dominated melt systems. In addition to Si and O, Ti, Al, Fe³⁺, Fe²⁺, Mn, Mg, Ca, Na, K and P comprise the constituents commonly referred to as the ‘major elements’. It has become conventional to refer to these in terms of their oxides, expressed in weight percent (Table 1). Furthermore, magmas typically contain dissolved volatile species, dominated by H₂O, but including SO₂, H₂S, Cl₂, F₂, CO₂, CO and traces of noble gases such as He, Ar and

Xe. Elements such as Rb, Sr, Ba, Zr, Nb, the rare earth elements, Pb, Th and U are present in trace amounts (typically µg g⁻¹ or ppm) and are called ‘trace elements’.

After magmas form, they may move away and separate from their source regions, due principally to

Table 1 Major oxide chemical analyses (wt%) of typical volcanic igneous rocks. All data are from the author's database of chemical analyses

Element oxide	Basalt	Andesite	Dacite	Rhyolite
SiO ₂	49.86	60.35	66.68	73.89
TiO ₂	1.38	0.78	0.58	0.33

Figure 1 (See Colour Plate 33). Crossed polarizer photomicrographs of (a) a glassy basalt, (b) a gabbro, (c) an andesite, (d) a diorite, (e) a rhyolite and (f) a granite. Each of these photographs was taken at the same magnification (horizontal field is 10 mm across). The bulk composition of the magma forming the basalt and gabbro are broadly similar, as is the bulk composition for the andesite and diorite and the rhyolite and granite. The minerals crystallizing from the basalt and gabbro are similar, as are those in the andesite and diorite and the rhyolite and granite. The clearly observable differences in texture result from differences in crystal growth and nucleation rates. (a) Basalt showing large crystals (phenocrysts) of plagioclase feldspar (grey), Ca-rich pyroxene (purple, at centre) and olivine (yellow, top left) in a finer grained groundmass of these minerals. (b) Gabbro showing crystals of Ca-rich pyroxene (red-orange) enclosing plagioclase (grey-white with multiple twinning) and olivine (blue, green and red grains right of centre). (c) Andesite showing phenocrysts of plagioclase (grey-white with multiple twinning) and pyroxene (yellow, orange-red) set in a fine grained glassy groundmass. (d) Diorite showing a rock comprised of plagioclase feldspar (grey-white multiply twinned crystals), pyroxene, amphibole (green) and interstitial quartz (yellow-grey). Note how the amphibole crystals form a jacket or coating on the pyroxene (centre). (e) Rhyolite showing perlitic cracking in glassy groundmass and phenocrysts of quartz and plagioclase (twinned). Note the corroded and resorbed grain boundaries of the phenocrysts. (f) Granite showing interlocking crystals of plagioclase (twinned), alkali feldspar (turbid, dusty appearance), quartz (clear) and biotite (speckly orange).

the fact that they are less dense and less viscous than their surroundings. Ultimately, they may be emplaced at shallower levels in the Earth, forming igneous intrusions such as batholiths, plutons and sills or erupted at the surface as lava flows or pyroclastic rocks.

Because they are multicomponent melt systems, on cooling, magmas will crystallize a variety of silicate minerals, whose composition is controlled by the bulk composition of the magma and whose grain size is determined by the rates of cooling and crystal nucleation (Figure 1). Thus basaltic magmas will

crystallize Ca-rich pyroxene, Ca-rich plagioclase, Fe-Ti oxides and perhaps olivine, whereas granitic magma will crystallize Na-rich plagioclase, K-rich alkali feldspar, quartz and mica. The ultimate example of undercooling is a natural glass, called obsidian in the case of rhyolite and tachylite in the case of basalt. In nature, volcanic rocks are frequently a mixture of crystals (which grew at depth in the earth) and glass (which quenched on eruption). Intrusive rocks are more likely to be crystalline, with the interlocking minerals displaying a variety of textures

Figure 2 (See Colour Plate 35). Mineral layering in the Rum Igneous Intrusion, NW Scotland. This photograph shows spectacular centimeter-scale mineral layering in Unit 14 of the Eastern Layered Series of the Rum Layered Igneous Intrusion. The Rum Intrusion forms one of a number of layered intrusions, including Skaergaard in East Greenland and The Cullins, on Skye, NW Scotland, which are part of the North Atlantic Tertiary Igneous Province. Now exhumed by the combined effects of erosion and uplift, these intrusions mark the site of crystallizing magma chambers ~ 60 million years ago, during the early rifting stages of the North Atlantic Ocean. The near horizontal layers were formed by sequential precipitation of crystals of different composition (principally plagioclase, pyroxene, olivine and spinel) on the floor of a magma chamber. The darker layers are rich in the minerals olivine and pyroxene, the lighter layers richer in plagioclase. Mimicking sedimentary rocks where the principal hydraulic agent of sorting is a water column, in layered intrusions magma was the hydraulic agent and dense minerals, like spinel and olivine, settled more rapidly than plagioclase, leading to units which are graded from spinel and olivine-rich bases to plagioclase-rich tops.

reflecting the crystallization history of the magma (Figure 1). The minerals crystallizing from the basalt magma are higher temperature solid solutions than those of the granite magmas, deriving from their bulk composition and the higher temperatures of basaltic magmas.

The pioneering high-temperature experimental studies on the effects of magmatic crystallization was undertaken by N.L. Bowen and coworkers during the first half of twentieth century and laid the foundations for understanding how magmas evolve by crystallization. Bowen's textbook, *The Evolution of the Igneous Rocks*, first published in 1928, remains the definitive exposition on the application of phase equilibria to the study of magmatic crystallization. In this book, Bowen championed the role of fractional crystallization as the process most responsible for producing diversity in magmatic rocks. This work received a considerable boost by the discovery of the Skaergaard Intrusion in East Greenland by L.R. Wager in 1931 and subsequent mapping of the intru-

sion by Wager and W.A. Deer. Here, graphic demonstration of the effects of crystal settling layering and the results of fractional crystallization were to spawn an array of terminology and another benchmark text, *Layered Igneous Rocks*. Layered igneous intrusions (Figure 2) are now known to be important examples of subvolcanic magmatic systems where the processes of magmatic differentiation have been preserved.

Phase diagrams remain the most elegant way of appreciating how magmatic crystallization proceeds. Figure 3 is the phase system diopside ($\text{MgCaSi}_2\text{O}_6$)–anorthite ($\text{CaAl}_2\text{Si}_2\text{O}_8$)–albite ($\text{NaAlSi}_3\text{O}_8$) at 1 atm. This system makes a simple proxy for a basaltic magma because it consists of the two major minerals in basalt, plagioclase feldspar (anorthite–albite solid solution) and Ca-rich pyroxene (diopside). The diagram is divided into two primary stability fields by the curved, arrowed line from 1275°C at e to $\sim 1100^\circ\text{C}$ at e' . The upper field is that of diopside, the lower field that of plagioclase (solid solution). The curved line delineates a cotectic of falling temperature

Figure 3 The phase system diopside–anorthite–albite at 1 atm. This system is a particularly useful analogue for the basaltic magma system as it comprises the two major minerals which crystallize from basalt magma, Ca-rich pyroxene (diopside, $\text{MgCaSi}_2\text{O}_6$) and plagioclase feldspar (solid solution, ss, between anorthite ($\text{CaAl}_2\text{Si}_2\text{O}_8$) and albite ($\text{NaAlSi}_3\text{O}_8$)). In this system cooling melts will evolve along the diopside–plagioclase cotectic from right (high temperature) to left (low temperature). Note that in a cooling, crystallizing magmatic system, a liquid (L1) will be in equilibrium with crystals of diopside and plagioclase of composition P1. With cooling, L1 will migrate to L2 and here L2 will be in equilibrium with crystals of diopside and lower temperature plagioclase, P2.

(in direction of arrows) and along which changing liquid compositions will be in equilibrium with diopside and progressively different (lower temperature) compositions of plagioclase. Liquids (L1 and L2) lying along the curve ($e-e'$) will be in equilibrium with diopside and two plagioclase compositions (P1 and P2) such that the lower temperature liquid L2 is in equilibrium with a lower temperature, more sodic, plagioclase (P2).

The process of magmatic fractional crystallization can also be demonstrated effectively through the use of geochemistry. For example, in Figure 4, two bivariate plots of SiO_2 and CaO versus MgO (all in weight percent) are shown for a hypothetical parent magma which is cooling and fractionating olivine [$(\text{Mg}_2\text{SiO}_4)_{90}(\text{Fe}_2\text{SiO}_4)_{10}$]. Note that removal and addition of olivine to the 'parent' magma results in changes to the compositions of the resultant melts. Addition of olivine produces MgO enrichment, removal (extraction) of olivine produces MgO -depleted melts. A further application of this approach is illustrated in Figure 5, which uses the total alkali ($\text{Na}_2\text{O} + \text{K}_2\text{O}$) versus SiO_2 diagram, often referred to

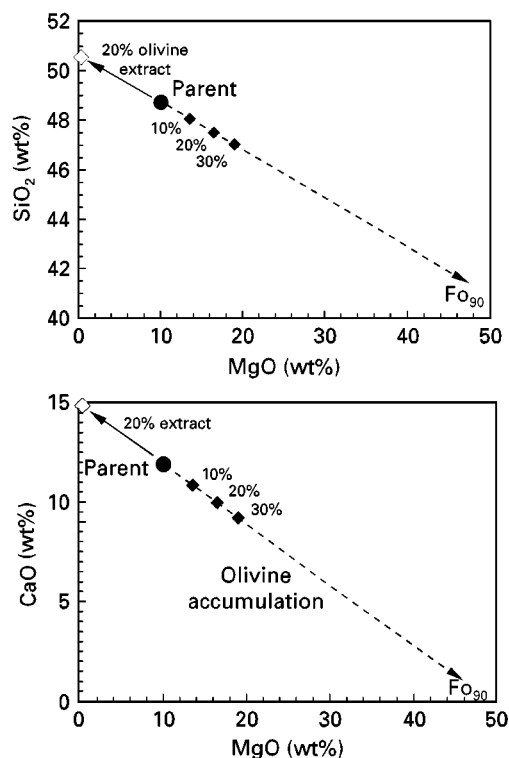

Figure 4 Chemical variation diagrams showing effects of olivine removal and addition to a hypothetical basalt parent magma. Olivine is a relatively simple orthorhombic silicate mineral and crystallizes as a solid solution of Mg_2SiO_4 (forsterite, Fo) and Fe_2SiO_4 (fayalite, Fa) end-members. In basaltic magmas, crystallizing olivine is typically Mg-rich, usually around Fo_{90} , consistent with the high temperatures of these magmas. Removal of Mg-rich olivine will rapidly deplete the residual liquid in MgO . Conversely, addition or accumulation of olivine in the melt will increase MgO .

Figure 5 Total alkalis ($\text{Na}_2\text{O} + \text{K}_2\text{O}$, wt%) versus SiO_2 (wt%) for a suite of chemically analysed volcanic rocks (\diamond) which have evolved from a parent (tephrite basanite) composition by fractional crystallization. The bifurcation in the trend derives from a change in the mineral proportions in the fractionating mineral assemblage, around 55–56% SiO_2 , one leading to phonolite the other leading to trachyte.

as the TAS diagram, and the internationally recommended means for classifying volcanic igneous rocks. Data points for a suite of analysed volcanic rocks have been added to this diagram and depict a trend of increasing total alkalis with increasing SiO_2 . Between 55 and 56% SiO_2 the trend splits, with one set of data showing relative enrichment in alkalis. These trends are readily explained by changes in the bulk composition of the fractionating mineral assemblages.

The importance of the process of crystallization in the evolution of magmas and igneous rocks is clear. Through fractional crystallization, which is the natural consequence of a cooling, crystallizing multicomponent magmatic system, a wide spectrum of compositions of igneous rocks can be produced. This, together with the depth at which partial melting takes place, is the major process responsible for producing diversity amongst terrestrial igneous rocks.

Introduction

Melt crystallization, sometimes referred to as ‘fractional crystallization,’ is a collective term for physical separation processes aimed at purification of organic compounds from a multi-component mixture by crystallization without addition of a solvent. The driving force for crystallization is created by cooling, evaporating or pressuring the melt.

The main advantage of this separation technique is the superior selectivity of the crystallization process caused by restricted mobility in the crystal lattice and strong molecular bonds. The energy consumption can be low because the heat of fusion of most organic compounds is two to four times smaller than their heat of evaporation and the operating conditions are generally mild. Finally, the absence of hazardous solvents is important from an environmental point of view. Disadvantages are the inherent slowness of crystal growth leading to voluminous equipment and the need for intensive slurry handling in certain process designs.

Balancing the merits and drawbacks, melt crystallization is usually applied for ultrapurification (> 99.99%), separation of isomers and purification of thermally unstable components. Some examples of industrial applications are acrylic acid, bisphenol A, caprolactam, cresol, dichlorobenzene, fatty acids, naphthalene, paraffin and xylene.

In this chapter, the designs of conventional and emerging melt crystallization processes are described and evaluated. Also the related field of freeze-concentration of aqueous solutions is briefly touched upon. Extensive coverage of all types of equipment on different scales is beyond the scope of this article. There is a focus on large-scale applications with a bias on state-of-the-art equipment provided by equipment manufacturers rather than the proprietary processes of end-users. More elaborate overviews of the principles and applications of melt crystallization are given in the Further Reading.

Theory

The technical feasibility and economic viability of separation and purification of an organic mixture by

melt crystallization entirely depend on its solid–liquid phase equilibrium (SLE). A survey of SLE data in 1986 demonstrated that more than 70% of organic substances have melting points between 0°C and 200°C, indicating that no special thermal media are needed to achieve separation (Figure 1).

The classification of about 1500 binary systems in the International Critical Tables (Figure 2) has revealed that more than 50% form simple eutectic mixtures and 25% form an intermolecular solid compound which forms simple eutectics with the two constituent components. This type also includes the formation of more than two solid compounds. The formation of a pure solid phase in one crystallization step is feasible for roughly 85% of the systems. The formation of solid-solutions is limited to only 10%, for which complete separation in a single crystallization step is fundamentally impossible.

Even for eutectic systems, however, the product from industrial crystallizers is not 100% pure. This is caused by the adherence of mother liquor to the crystal surface and by the inclusion/entrapment of mother liquor inside the crystals. Further purification is required and this can be achieved by washing and by sweating.

- Washing is done by contacting the crystals with a fresh solvent or, preferably, with pure melted product. This operation removes adhering impurities and is widely used in commercial plants.
- Sweating can be induced by exposing the impure solid phase to slightly elevated temperatures. This operation removes locally dispersed included impurities. Upon a temperature increase, the fraction of liquid inside the crystals increases according to the lever-rule whereby the more impure sections

Figure 1 Distribution of atmospheric melting points of organic components (after Matsuoka and Fukushima, 1986).

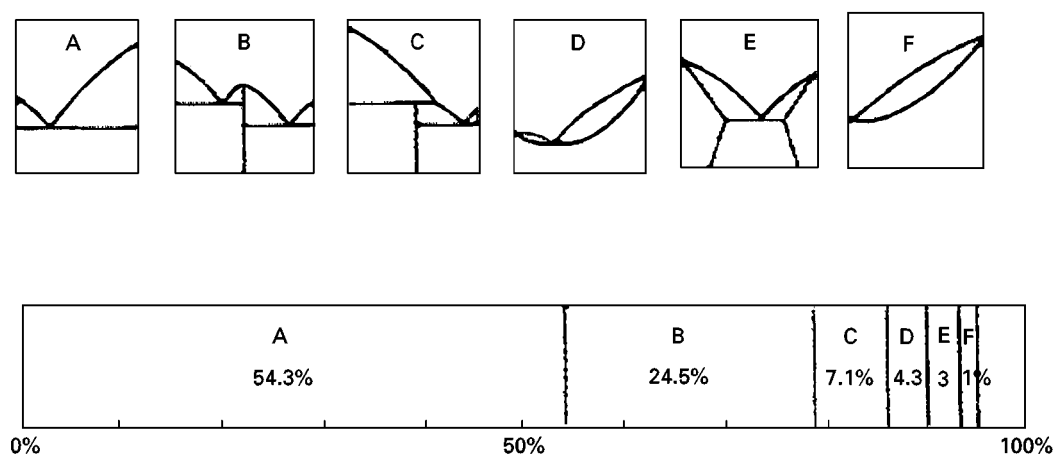

Figure 2 Distribution of binary phase diagrams of organic mixtures (after Matsuoka and Fukushima, 1986).

melt preferentially due to a lower melting point. The impure liquor comes out of the crystalline body through cracks and pores. Sweating can also be applied to solid solution systems and plays an important role as a purification mechanism in layer and suspension growth processes.

Process and Equipment Design

Indirect cooling is the most widely applied technique to produce crystals from a melt. In this context the term 'indirect' refers to the mechanism of heat transfer from the melt to the cooling medium, which takes place via the wall of a heat exchanger. Crystal growth may either take place as a layer on a cooled surface or freely suspended in the mother liquor. The principles of both techniques and their large-scale applications are discussed below. See Table 1 for an overview and an evaluation of both techniques.

Layer Growth

In this technique the crystals grow as a layer fixed and perpendicular to a cooled wall. The heat of crystallization is removed through the crystal layer and the wall. At low growth rates (typically $< 10^{-7} \text{ m s}^{-1}$) and proper mixing of the mother liquor, a stable crystal morphology can be maintained, which results in a good selectivity of the crystallization step. In industrial practice, however, very high growth rates (10^{-6} – 10^{-5} m s^{-1}) must be applied leading to roughening of the crystal surface (cellular and dendritic growth) and consequently to entrapment of impure liquor in the layer. High growth rates are required to achieve a reasonable productivity since the growth area is limited to the heat-exchange area ($\leq 100 \text{ m}^2 \text{ m}^{-3}$).

Industrial layer growth equipment is normally operated batch-wise, whereby static and dynamic processes can be distinguished. In *static equipment*, crystal growth occurs from a stagnant melt. Commercial equipment is manufactured by BEFS Technologies (France) and Sulzer Chemtech (Switzerland). Their similar designs feature a closed rectangular vessel equipped with a high heat-exchange area in the form of finned tubes or structured plates (Figure 3). One full operating cycle takes about one day and comprises five steps: (1) filling of the vessel, (2) crystallization by programmed cooling, (3) sweating by gradual heating, (4) draining of residual mother liquor and (5) melting and draining of the product layer. Equipment sizes range from 0.1 to 35 m^3 . Typical growth rates are in the order of 10^{-6} m s^{-1} but the overall separation efficiency of a full operating cycle is relatively good (up to 99.9 wt% product purity).

In *dynamic processes*, there is forced mixing of the mother liquor during the crystallization step. The mixing is usually achieved by circulating the liquor as a falling film or as a fully developed flow over vertical heat-exchanger tubes. Other designs whereby mixing was achieved by stirring, pulsation or bubbling-through an inert gas, were not successfully commercialized. Sulzer Chemtech provides the dynamic falling film system whereby both the melt as well as the coolant are circulated as falling films over the tube wall (Figure 4).

The turbulent flow regime of the mother liquor enhances heat and mass transfer, which enables higher growth rates of typically 10^{-6} – 10^{-5} m s^{-1} . Similar to the static process, one full operating cycle comprises five stages but is completed in 1.5 h. Tubes are about 0.1 m in diameter and 12-m long while up to 1250 tubes are fitted in one shell.

Table 1 Comparison of layer and suspension growth processes (values represent order of magnitude; operation/maintenance relative to distillation)

Parameter	Layer growth	Suspension growth
Crystal surface area	Up to $100 \text{ m}^2 \text{ m}^{-3}$	Up to $10\,000 \text{ m}^2 \text{ m}^{-3}$
Growth rate	10^{-6} – 10^{-5} m s^{-1}	10^{-8} – 10^{-7} m s^{-1}
Mixing intensity	Poor (static)/good (dynamic)	Good
Separation efficiency	Good (static)/moderate (dynamic)	Excellent
Product purity in one stage	$\leq 99.9\%$	$\geq 99.95\%$
Mode of operation	Repetitive batch	Once through, continuous
Heat transfer coefficient	$\sim 200 \text{ W m}^{-2} \text{ K}^{-1}$	$\sim 1250 \text{ W m}^{-2} \text{ K}^{-1}$
Energy efficiency	Good (static)/moderate (dynamic)	Good
Slurry handling	No	Yes
Solid-liquid separation	No	Yes
Design	Simple	Complex
Operational attention	Normal	Above average
Maintenance intensity	Normal	Above average
Scale-up	Multiplication of units	Engineering
Economy of scale	Not good	Good
World-scale plant capacity	$\sim 150 \text{ kT year}^{-1}$	$\sim 350 \text{ kT year}^{-1}$
Feed concentration	Preferably $> 90\%$	Preferably $< 99\%$
Viscosity	$< 10 \text{ cP}$	$< 50 \text{ cP}$
Purification of solid solutions	Suitable	Less suitable
Freeze concentration	Less suitable	Suitable

The overall separation efficiency of one dynamic operating cycle is moderate relative to a static process but the short cycle time makes the dynamic process well suited to sequential countercurrent staging. Staging requires intermediate storage tanks but makes it possible to produce ultrapure products at good recov-

ery. The stages are actually operating cycles which can be executed in the same crystallizer (Figure 5).

One of the drawbacks of the dynamic process until now has been its poor energy efficiency resulting from the need to repeatedly crystallize and melt a product to attain the desired purity. This problem was

**Figure 3** Static crystallizer. (Courtesy of Sulzer Chemtech.)**Figure 4** Dynamic falling film crystallizer. (Courtesy of Sulzer Chemtech.)

Figure 5 Multistage operation of layer growth processes (temperatures $T_1 < T_2 < T_3$).

addressed by the introduction of heat integration in 1996. The principle is based on a heat pump where a crystallizer alternatively acts as a condenser or as an evaporator for the cooling agent (Figure 6).

Continuous processes, whereby the layer growth occurs on a rotary drum or an endless belt, have been designed but are not applied commercially for purification of organics for various reasons (low selectivity, mechanical complexity, economy of scale).

Static and dynamic layer growth equipment are applied commercially to a wide range of products (e.g. acrylic acid, *p*-xylene, naphthalene, bisphenol A and paraffin). A relatively high feed purity is required, particularly for the dynamic processes, since this promotes the adhesion of the crystal layer to the cooled surface.

Suspension Growth

In this technique, the crystals form and grow freely suspended in the mother liquor. The heat of crystallization is absorbed by the supercooled liquor. High

specific productivity can be achieved at low growth rates because the crystal surface area is very large (up to $10\,000\text{ m}^2\text{ m}^{-3}$). Typical growth rates in industrial units are only 10^{-8} – 10^{-7} m s^{-1} which contributes to an excellent selectivity of the crystallization process.

Suspension growth processes generally comprise separate sections for crystallization and solid–liquid separation. The effectiveness of the final solid–liquid separation has a major impact on the overall separation efficiency. The design of the crystallization section should be focused therefore on producing crystals with a good filterability which means essentially growing large crystals with a narrow size distribution. The fundamentals of modelling particulate processes are also applicable to suspension growth from the melt.

Crystallization section Single-stage crystallization is often unfavourable because the nucleation and growth of all crystals occurs at the lowest operating temperature, which is determined by the yield, from an impurity-rich mother liquor. The simplicity of this design often does not outweigh the potential disadvantages:

- poor filterability of crystals due to high nucleation : growth ratio;
- reduced selectivity due to inclusion or incorporation of impurities;
- moderate energy efficiency;
- difficult solid–liquid separation.

Cascades of crystallizers, operated either cocurrent or countercurrent, are found in most processes. In *cocurrent cascades* crystals and mother liquor are transported in parallel from stage to stage at decreasing temperature. The GMF-CDC (Figure 7) is an example of a cocurrent cascade, where the crystal slurry flows freely from one compartment to the next via openings in the cooling elements. Along the flow direction, the impurities are concentrated in the mother liquor but the nucleation rate and the crystal growth rate decrease. As a result, the filterability of the crystals improves throughout the cascade while a good selectivity is maintained. The product crystals suspended in the impure mother liquor are withdrawn from the cold end of the cascade, which is a major drawback for solid–liquid separation.

In *countercurrent cascades* crystals and mother liquor are transported in opposite directions. TSK (Japan) and Niro-PT (Netherlands) provide similar countercurrent cascades, although the design of the individual stages differs considerably (Figure 8; see also Figure 17). The feed is usually supplied to the hot end of the cascade making sure that here too a large

Figure 6 Heat integration of dynamic falling film crystallizers. (Courtesy of Sulzer Chemtech.)

Figure 7 Cocurrent cascade of crystallizers. (Courtesy of GMF-Gouda.)

part of the crystal production occurs at high temperature from a relatively pure mother liquor. Purification of the crystals by Ostwald ripening (growth of large crystals by dissolution of fines driven by a reduction of surface energy) can play a role but it is doubtful whether there is a contribution from sweating. Product withdrawal occurs from the hot end, which simplifies solid-liquid separation.

A comparison of cocurrent and countercurrent crystallizers is shown in Table 2.

Solid-liquid separation section Product recovery is more and more executed in wash columns, which combine an effective solid-liquid separation with a pure melt wash and a single recrystallization step. The principle of wash columns is illustrated by Figure 9. A crystal slurry is pumped into the column, where the mother liquor escapes via a filter leaving behind the crystals as a packed bed. This bed is transported upwards by means of a rotating screw. At the top, the crystals are scraped off, suspended in wash liquid (recycled pure melt) and melted in an external melter. The wash-liquid circuit is kept pressurized, which causes the wash liquid to flow downward (reflux). The wash liquid does not leave the column but recrystallizes on the cold crystal bed, thereby producing the so-called 'wash front'. This front marks steep gradients in concentration, temperature and porosity.

Figure 8 Countercurrent cascade of crystallizers. (Courtesy of Tsukishima Kikai Co. (TSK).)

The crystal bed can be transported under gravity, by hydraulic pressure or via a mechanical aid (screw/piston). The direction of transport is normally downwards for organic crystals and upwards for ice.

If the temperature of the feed slurry is low (single-stage or cocurrent cascade crystallization), more wash liquid will recrystallize causing a large drop in porosity over the wash front. At a given transport force exerted on the crystal bed, the throughput reduces with decreasing porosity due to an increased back-pressure from the wash liquid. Alternatively at constant throughput, the compressive stresses exerted on the crystals increase considerably which may result in deformation of some organic crystals, which are mechanically weak. Ideally, the temperature increase over a wash column should be 2–5°C.

Mass and heat transfer in the wash columns are governed by axial dispersion of the liquid phase while

Table 2 Comparison of crystallization sections consisting of a single-stage, a cocurrent cascade or a countercurrent cascade

Parameter	Single	Cocurrent	Countercurrent
Operating temperature	Constant low	Decreasing	Increasing
Product withdrawal	Cold	Cold end	Hot end
Product crystal filterability	Moderate	Good	Good
Product liquor	Impure	Impure	Relatively pure
Internal slurry handling	None	Limited	Intensive
Equipment and process design	Simple	More complex	Complex

Figure 9 Principle of wash column. (Courtesy of Niro-PT.)

heat-transfer limitation in the solid phase may be neglected. In the more densely packed hydraulic and mechanical wash columns, purification occurs almost exclusively by displacement washing. In the loosely packed gravity wash columns, further purification by sweating occurs because of the longer residence time.

Gravity and mechanical wash columns have been commercialized by TSK and Niro-PT, respectively. TNO (Netherlands) has developed a hydraulic wash column equipped with separate filter tubes. See **Figure 10** and **Table 3** for a more detailed comparison.

Suspension growth equipment is applied commercially to purify various organic products (e.g. *p*-xylene, naphthalene and *p*-dichlorobenzene) but also for concentration of aqueous solutions (freeze concentration, see below). There are virtually no restrictions on feed purity, while a product purity $\geq 99.99\%$ is feasible.

Column crystallizers Column crystallizers are designs where a single-stage crystallizer and a gravity-wash column have been integrated in one shell (similar to distillation columns). The back-mixing column, for example, has been successfully commercialized by Nippon Steel Chemical Co. (Japan) for the purification of naphthalene. The pro-

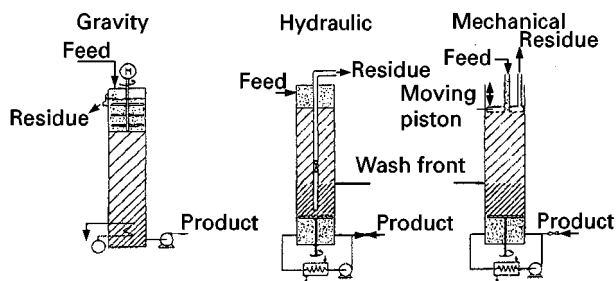

Figure 10 Classification of wash columns based on the crystal transport mechanism (after Jansens and Van Rosmalen, 1994).

duction rate is limited by the capacity of the wash columns ($\leq 1500 \text{ kg m}^{-2} \text{ h}^{-1}$). A new development by Matsuoka is the inclined column crystallizer. The inclination promotes settling and reduced axial dispersion (**Figure 11**).

Alternative Process Designs

Evaporative Melt Crystallization

Direct cooling is the driving force for evaporative crystallization. The heat of crystallization is withdrawn by evaporation of a portion of the mother liquor, which is induced by a reduction of the operating pressure. The vapour phase is condensed in an overhead condensor and refluxed to the crystallizer. Crystal formation and growth take place freely suspended in the bulk of the mother liquor. The main advantage of direct over indirect cooling is that the heat of crystallization is transferred to the cooling medium via a clean condensing duty rather than via a (scrapped) heat exchanger. Hence the heat transfer is more effective while the design and scale-up of equipment can be simplified.

In conventional evaporative crystallization processes, low boiling solvents (propane and carbon dioxide) are used to crystallize heavier organic components but the addition of solvents is not desirable for various reasons (equipment size, safety and the

Table 3 Comparison of wash columns

Parameter	Gravity	Hydraulic	Mechanical
Height : diameter ratio	4–6	1	1
Minimum crystal size	500 μm	150 μm	150 μm
Residence time: whole column	1 h	10–15 min	10–15 min
Residence time: wash section	30 min	3–5 min	3–5 min

environment, product purity). The potential of applying direct cooling to melt crystallization, however, was not recognized until recently.

In 1993 TSK proposed a purification processes based on evaporative melt crystallization for caprolactam, acrylic acid and bisphenol A. Figure 12 illustrates the set-up of a continuous process featuring a single-crystallization stage and a wash column (purifier).

In recent years, a batch-wise evaporative melt-crystallization process with caprolactam–water as a model system has been developed and optimized. Figure 13

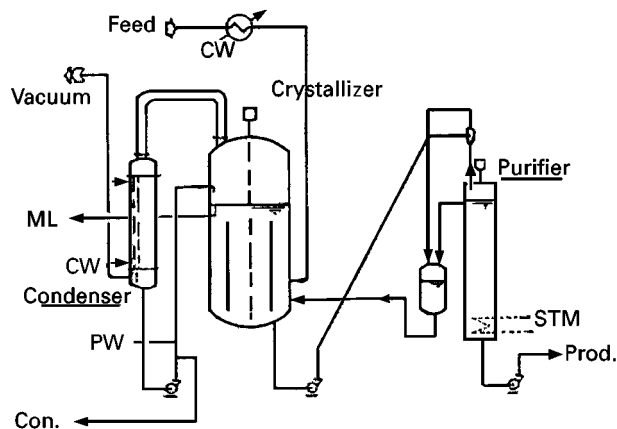

Figure 12 Continuous evaporative crystallization. ML, mother liquor; Con., condensate; Prod., product; STM, steam; CW, cooling water. (Courtesy of Tsukishima Kikai Co. (TSK).)

shows the pressure temperature–fraction temperature (PT–XT) phase diagrams where the three-phase equilibrium curve (S_{CLV}) stretches from the triple point of caprolactam (T_c) to the quadruple point of the binary system (T_q). Lowest operating cost can obviously be achieved near 5 wt% water, where the operating pressure is maximum and the temperature fairly high. Deep vacuum would be required for water concentrations below 1 wt% and above 20 wt%. Operating at a high temperature generates cost savings for the condenser (low area, no chilled cooling water).

Figure 14 shows the PT-trajectory for the batch-wise crystallization of caprolactam from a melt containing 4 wt% of water. Starting from point A, the pressure in the crystallizer is reduced until the vapour–liquid equilibrium is reached at point B and the melt starts to boil. Upon a further reduction of pressure, the evaporation of mainly water causes the melt to cool down but the composition of the melt does not change since the vapour is condensed and refluxed. At point C the solid–liquid–vapour equilibrium is reached and caprolactam starts to solidify. From C to D the crystal content steadily increases to 20 wt%, while the water concentration in mother liquor increases to 5 wt%.

Scale-up to 50–100 m³ crystallizers appears to be feasible, which is world scale for suspension crystallization equipment. Until now, there are few commercial installations with limited capacity. TSK has installed two units for caprolactam with a capacity of 2500 tons per year.

Pressure Crystallization

In this technique, crystallization is induced by compression rather than by cooling. The solid phase of most (organic) materials has a higher density than the liquid phase and consequently the melting point rises with increasing pressure. Benzene, for example, has an atmospheric melting point of 5.5°C but solidifies at room temperature when the pressure is about 2 MPa. Not only the melting points but also solid–liquid phase equilibria shift upward upon a pressure increase, which is illustrated for a mixture of cresols in Figure 15.

An additional advantage of pressure crystallization is found in the transmission of pressure being much faster than the transfer of heat in both liquid and solid phases. This means that a uniform pressure can be established quickly throughout the system. Therefore local variations in supercooling of the mother liquor can easily be avoided.

The separation of cresol isomers by conventional (atmospheric) cooling crystallization is rather difficult due to a high viscosity of the melt. Kobe Steel

Figure 13 Pressure-temperature-composition diagram of ϵ -caprolactam-water. (Reproduced with permission from Diepen PJ (1998) *Cooling Crystallization of Organic Compounds*. PhD thesis, Technical University Delft.)

(Japan) developed in the 1970s a pressure-crystallization process, which was applied for the separation of p -cresol from its isomers on a commercial scale. A given amount of slurry from a chiller is fed to a cylindrical pressure vessel, compressed to crystallize and drained to remove residual impure melt (Figure 16). During the subsequent depressuring, purification by sweating can occur. Finally, a cylindrical block of purified crystals is taken out as the product. The operating temperature is 62.5°C at 200 MPa (versus 12.5°C at atmospheric pressure) which effectively reduces the viscosity of the mother liquor. Under these conditions, the selectivity and the rate of crystal growth rate are enhanced while solid-liquid separation is facilitated. Purification by sweating during depressuring is analogous to (thermal) sweating at elevated temperatures.

The features of pressure crystallization can be summarized as follows:

- batch-wise operation;
- product purity up to 99.5%, feasible in one operating cycle from 70 to 80% in feed;

Figure 14 Part of pressure-temperature diagram of ϵ -caprolactam-water. (Reproduced with permission from: Diepen PJ (1998) *Cooling Crystallization of Organic Compounds*. PhD thesis, Technical University Delft.)

- high yield, limited only by the solid-liquid equilibrium of a given system;
- short cycle times, only a few minutes per cycle, due to rapid penetration of pressure;
- low energy consumption – only mechanical energy used for compression;

Figure 15 Phase diagram of mixture of p -cresol and m -cresol. (Reproduced with permission from Yasuda M, Sato Y and Suematsu H (1991) p -Cresol with high pressure crystallization. *Kagaku Kogaku* 55(4): 290-291.)

Figure 16 Operating cycle of pressure crystallization process. (Reproduced with permission from Yasuda M, Sato Y and Suematsu H (1991) *p*-Cresol with high pressure crystallization. *Kagaku Kogaku* 55(4): 290–291.)

- simple process design – crystallization, separation and sweating are carried out in a single vessel;
- complex mechanical design – materials selection and construction of mechanical parts are critical factors for success.

The scale-up of pressure-crystallization equipment is not easy due to mechanical complexity, and it becomes increasingly difficult at larger vessel diameters to remove residual melt from the centre of the cake by compression. The production capacity of a single plant is in the order of 500 tons per year.

Freeze Crystallization

Freeze concentration is a separation technology aimed at concentration of aqueous solutions by means of cooling crystallization. This technology is closely related to melt crystallization based on sus-

pension growth in terms of process synthesis and equipment design.

Commercial processes feature a countercurrent cascade of crystallizers while the final solid–liquid separation takes place in mechanical wash columns (**Figure 17**). Indirect cooling is usually preferred over direct cooling to prevent contamination of the concentrate and to contain the volatile components. Large spherical ice crystals can be grown relatively easily through Ostwald ripening. The individual stages of the cascade therefore feature separate sections for nucleation and growth. Crystallization (nucleation) takes place on the surface of the external scraped surface heat exchangers. Ripening (growth) occurs in large stirred vessels.

Nearly identical process flow schemes and equipment designs can also be found in some melt-crystallization processes, e.g. to separate *p*-xylene from its isomers.

Figure 17 A three-stage countercurrent freeze concentration process. (Courtesy of Niro-PT.) (A) Simplified process flow scheme. (B) Cross-section of a scraped surface heat exchanger. °Bx is a measure for concentration of water phase (based on the breaking index).

Traditionally, most applications are found in the food industry for the concentration of fruit juice, wine, beer and coffee extract. In this field, the advantages of freeze concentration over competing technologies (membranes and evaporation) are the superb preservation of aromas and colour while decay reactions are slowed down by the low operating temperature.

Recently, world-scale installations have come on-stream where wastewater from chemical plants is concentrated. The produced melt water can be re-used as process water while the residual concentrate is incinerated. Here the advantages of freeze concentration are the low energy costs and the capability to concentrate beyond the eutectic point, where salts start to precipitate.

Drawbacks of freeze crystallization are the relatively high investment cost and the above-average maintenance intensity (there are many pieces of rotating equipment).

Conclusion and Future Outlook

Melt crystallization is the third most applied physical separation technology after distillation and extraction. Conventional processes are based on layer or suspension growth by indirect cooling.

- *Layer growth* may be considered as proven and mature technology, whereby the absence of slurry handling is a major advantage. Fully automated semi-continuous units can be delivered as turnkey projects. The need for repeated recrystallization steps to achieve a high product purity, however, increases both investment and operating cost. The desire to develop economically attractive continuously operated equipment seems to be in conflict with the basic characteristic of layer growth on a cooled surface.
- *Suspension growth* is also proven but not yet mature technology. The superior selectivity and high

specific productivity of crystal growth in a suspension create a huge potential, which can be further exploited by simplification of equipment design and minimization of slurry handling.

- *Evaporative melt crystallization* is a relatively young technology which combines the merits of suspension growth with a minimum of slurry handling. For certain applications, such as caprolactam, this technique is expected to take off in coming years.
- *Pressure crystallization* is an alternative technology, which is well suited to purify components with a very low melting point at ambient temperature but elevated pressure. Outside this niche use, pressure crystallization probably cannot compete with indirect/direct cooling crystallization due to high equipment cost.

Polymorphism

M. R. Caira, University of Cape Town, Rondebosch, South Africa

Copyright © 2000 Academic Press

Introduction

When the molecules of a chemical substance are able to crystallize in more than one three-dimensional

structure arrangement, the substance is said to display polymorphism. This phenomenon was discovered in the early nineteenth century but only since the middle of the twentieth century have its wider implications been appreciated by scientists investigating the crystallization, properties and interconversion of solid phases. These implications stem from the fact that different polymorphs of a given substance may

display very significant differences in physical properties such as melting point, colour, hardness, density, electrical conductivity, heat of fusion, solubility and dissolution rate, as well as differences in chemical reactivities. Polymorphism is a common phenomenon which has vital ramifications in the crystallization and processing of pharmaceuticals, in food chemistry, explosives manufacture and in crystal engineering. The profusion of polymorphic forms that might be encountered for a single compound (e.g. up to ten in some instances) has often been viewed as an unwelcome source of confusion, threatening to undermine reproducible isolation of a specific crystalline form. However, those engaged in the study of polymorphism see the benefits this diversity of forms may offer. At the same time, it is recognized that in order to control the polymorphic outcome of the crystallization process, systematic research aimed at a full understanding of the interplay of thermodynamic, kinetic and structural factors involved is paramount. This is a daunting task, however, since the phenomenon of polymorphism is acknowledged to be a complex one with many questions as yet unanswered. Further progress depends critically on a multidisciplinary approach.

Terminology/Nomenclature

Figure 1(A)–(C) are schematic illustrations of different polymorphs of a compound. In (A) and (B), the molecular conformation is retained but the crystal structures are different. The occurrence of a form such as (C), in which the molecule crystallizes with a significantly different conformation gives rise to the term ‘conformational polymorphism’. In addition to

the possibility of forming different (but chemically identical) polymorphs, the molecules of a given substance may upon crystallization from solution incorporate solvent molecules (stoichiometrically or non-stoichiometrically) in the resulting crystal structure. These solvated crystalline forms (examples shown schematically in Figure 1(D) and (E)) are often referred to as ‘pseudopolymorphs’ and are no less important in practice than polymorphs of the parent substance. Thus, for a single organic compound, it is frequently possible to crystallize from solution a series of polymorphs as well as a series of pseudopolymorphs (in the latter case species containing different solvent molecules, either individually or as mixtures). Furthermore, it is possible for a compound to yield pseudopolymorphs which are chemically identical, but structurally distinct (e.g. a monoclinic dihydrate and an orthorhombic dihydrate). Such species may be considered as polymorphic pseudopolymorphs. Since physical properties are ultimately dependent on crystal structure, each of these species will therefore have unique properties. It is also noteworthy that the desolvation (e.g. by controlled heating) of pseudopolymorphs such as those in Figures 1(D) and (E) would yield polymorphs of the parent compound. Hence, this represents another route to isolation of polymorphs in addition to crystallization from solution, melt or vapour.

In the above descriptions of polymorphism and pseudopolymorphism, the simplest connotations of these terms have been used and a digression into semantics has deliberately been avoided. However, it is important to note that difficulties with terminology do arise due to inconsistent use and the multiplicity and overlap of synonymous terms (e.g. ‘crystal form’

Figure 1 Schematic diagram illustrating polymorphism (A)–(C) and pseudopolymorphism (D), (E); Filled circles represent included solvent molecules.

and 'crystal modification' as synonyms for polymorph; 'solvate', 'inclusion compound', 'clathrate' for pseudopolymorph). Pharmaceutical chemists tend to use 'polymorph' to describe a one-component system and 'pseudopolymorph' for a multi-component system. Finally, it should be noted that amorphous (non-crystalline or 'glassy') states of matter are also relevant in the context of polymorphism, since such phases may arise during transformation of one polymorph into another or during trituration of a crystalline polymorph. Amorphous phases are thermodynamically unstable and will tend to undergo spontaneous crystallization to yield a stable polymorph.

Polymorphic Crystallization and Polymorphic Transformations

Thermodynamic Aspects of Polymorphism

Thermodynamic treatment of a system displaying polymorphism is based on considerations of the Gibbs free energy, G_i , of each polymorph as well as the variation of G_i with the thermodynamic variables temperature (T) and pressure (p). Furthermore, since each polymorph is distinct, each has a characteristic value for its entropy, S_i (≥ 0), under any given conditions of T and p . Considering constant pressure, the thermodynamic relationship $(\partial G_i / \partial T)_p = -S_i$ therefore indicates that the slope of the G - T curve for each polymorph of a compound at any given value of T is (a) negative and (b) different. The stable phase at any given temperature is that polymorph with the lowest value of G , and since the G - T curves for the various polymorphs will generally intersect one another at various temperatures owing to their different slopes, it follows that at a given T , one polymorph will be stable and all others metastable with respect to it. When two G - T curves intersect, the polymorphs they represent are in thermodynamic equilibrium at their transition temperature (T_t) and these phases then have identical values for their Gibbs free energy. Each polymorph thus has a temperature range within which it is stable. (From a thermodynamic viewpoint, the co-existence of several polymorphs of a given substance at e.g. 1 atm, 25°C is a paradox; the reason that this situation arises frequently in practice is that the activation energies for solid-solid transformations to the stable phase are generally very high and such transitions are therefore under kinetic control).

The general principles outlined above can be applied to a dimorphic system, for which the thermodynamic behaviours are classified as being either enantiotropic or monotropic, each of which has practical implications as far as interconversion of the two

polymorphs is concerned. Figure 2 illustrates these cases. Here A, B, and L denote the lower and higher melting polymorphs and their common liquid phase respectively. Intersections of the Gibbs free energy curves of A and B with that of L coincide with the respective melting points $T_{m,A}$ and $T_{m,B}$. In the case of enantiotropy, the curves for A and B intersect at the transition temperature T_t which lies below either of the melting points; furthermore, on either side of T_t , the stability order of A and B is reversed. Each polymorph therefore has a temperature range in which it is stable and the transition between the two is reversible. In practice, processing conditions which involve temperatures near T_t could therefore induce a polymorphic transformation from one stable form to the other (which may or may not be desirable). In the monotropic system, the higher melting polymorph (B) is always the more stable one and the other (A) is metastable with respect to it. If a metastable polymorph is prepared, it may spontaneously convert to the more stable polymorph under conditions conducive to phase transformation.

Using experimental data from differential scanning calorimetry (DSC) together with the thermodynamic relationship $G = H - TS$, the simple curves of Figure 2 can be resolved into their constituent curves depicting the variation of the individual terms H and TS with temperature. An example of such a diagram is shown in Figure 3. Such a composite 'energy/temperature' diagram for a dimorphic system, which includes the curves for both polymorphs, was recommended by Burger and Ramberger in 1979 as a valuable aid in the interpretation of thermal data and for determining polymorphic stability relationships. A set of rules supported by arguments based on statistical mechanics was subsequently formalized from consideration of such diagrams. These rules were intended to be applied in practical situations to determine whether a polymorphic system is enantiotropic or monotropic. For example, according to the 'Heat-of-Transition' Rule, observation of an endothermic effect in a dimorphic system implies the existence of a transition point below it, which in turn requires the dimorphs to have an enantiotropic relationship. In practical cases, where the heat of transition is not measurable due to the slow rate of transformation, the melting points and heats of fusion of the low- and high-temperature polymorphs are determined separately by DSC. The difference between the heats of fusion may then be used instead as an estimate of the heat of transition, leading to a special case of the above rule called the 'Heat-of-Fusion' Rule. A 'Density Rule' relating polymorphic density to thermodynamic stability, and the 'Infrared Rule' which allows entropy rankings from observations of specific

Figure 2 Gibbs free energy-temperature relationships in dimorphic systems. Symbols are defined in the text. (Reproduced with permission from Yu L (1995) *Journal of Pharmaceutical Science* 84: 966, Copyright American Chemical Society and American Pharmaceutical Association.)

infrared frequencies for hydrogen bonded molecular crystals, were also formalized. In more detailed studies of polymorphism, these rules are often applied in an attempt to deduce relative thermodynamic stabilities in a dimorphic pair (especially to determine which is the more stable species at room temperature). Exceptions to the rules are known (conformational polymorphism being acknowledged as a complication) and this may account for the fact that they are not applied universally when the necessary ther-

mal data are available. In 1995, Yu addressed the issue of inferring thermodynamic stability relationships for polymorphs from thermal data using a purely thermodynamic approach. This led to formulae for calculating the Gibbs free energy difference between the polymorphs, ΔG , as well as its temperature derivative. The relative stability of polymorphs can thus be estimated by extrapolation of the value of ΔG to any desired temperature. This work also provided a critical comparison of the derived 'thermodynamic' rules

Figure 3 Schematic energy diagram for RG 12525 polymorphs I and II which are enantiotropically related. Copyright American Chemical Society and American Pharmaceutical Association.)

with those of Burger and Ramberger showing that, with little exception, they are effectively equivalent, despite the different routes for their derivation. It is likely that this recent endorsement of the Burger and Ramberger rules will lead to more frequent attempts to classify polymorphic systems in terms of enantiotropy or monotropy. A further important outcome of the more recent treatment is that the transition temperature, T_v , is easily estimated by extrapolating the value of the temperature-dependent quantity $\Delta G(T)$ to zero. Knowledge of the value of T_t for a pair of polymorphic forms is of practical importance in the case of enantiotropy and of theoretical interest in the case of monotropy, since for the latter, it is a virtual temperature.

Solubility data provide an alternative means of determining polymorphic transition temperatures. Over a small temperature range, a plot of \ln (solubility) against $1/T$ (a van't Hoff plot) for a polymorph is linear, with a slope related to the enthalpy of dissolution. If the solubility data for two polymorphs of the compound in a common solvent are treated in this way, the point of intersection of the plots will yield the polymorphic transition temperature T_t . An example is illustrated in Figure 4. Furthermore, the heat of transition (ΔH_t) may be calculated as the

difference between the enthalpies of dissolution, since dissolution of either of two polymorphs A and B (distinguishable only in the solid phase) leads to the same species in solution. The above description neglects a common practical problem, namely the possibility

Figure 4 van't Hoff plots for Piretanide Forms A and B at pH 5: ○, Form A; ●, Form B. (Reproduced with permission from Chikaraishi Y, Otsuka M, and Matsuda Y (1995) *Chem. Pharm. Bull.* 43: 1966, Copyright Pharmaceutical Society of Japan.)

of solvent-mediated polymorphic phase transformation during solubility measurement. This type of transformation is but one of several which polymorphs may undergo.

Kinetics of Nucleation and Polymorphism/Pseudopolymorphism

A prerequisite for crystallization of a specific polymorphic phase is the formation of viable nuclei of that phase, nuclei being defined as the smallest molecular aggregates with a configuration resembling that of the final crystal. The probability of nucleation occurring increases with increasing supersaturation of the solution; in such a solution, where incipient nuclei of all possible polymorphs may exist, kinetic factors determine which of these will become viable, i.e. lead to crystallization of a specific polymorph. The critical parameter associated with the formation of a nucleus is the Gibbs free energy of activation, ΔG^* . Nucleation, which proceeds with a rate dependent on ΔG^* , may occur heterogeneously or homogeneously depending on whether random impurities or substrates promoting nucleation are present or not. In the former case, the mechanism of nucleation is associated with a reduction in ΔG^* , relative to the uncatalysed process.

A detailed treatment of homogeneous nucleation shows that the value of ΔG^* is determined by several factors including a geometrical factor specific to the shape of the nucleating cluster, the molecular volume, the interfacial energy (between the nucleating cluster and the crystallization medium), and the chemical potential difference between the crystal and the medium. The crucial point that emerges as regards crystallization of different polymorphs of a given compound from a given medium is, that for each polymorph the values of the various individual factors affecting ΔG^* generally differ. This emphasizes the competitive nature of polymorphic crystallization. In this context, Ostwald's law of stages predicts that nucleation of metastable forms will successively precede that of the stable form, but this has been shown to be valid only in limited regions of chemical potential difference. Since much has still to be learnt regarding evaluation of the individual parameters affecting ΔG^* for individual polymorphs, the problem of predicting polymorphic outcome on the basis of nucleation kinetics remains a complex issue which is receiving continued attention. Molecular dynamics methods have also been applied to the nucleation process with some success. Simultaneous precipitation of different polymorphs occurs frequently in industrial crystallizations. Recent theoretical modelling of this type of process for a dimorphic system has

indicated that polymorphic composition depends on the ratio of the nucleation rates, the ratio of the growth rates and the aggregation tendencies of the two polymorphs.

Crystallization of the solute alone from the medium has been considered thus far. Solvation plays a major role in the crystallization of pseudopolymorphs from solution. Here, the enthalpic advantage associated with particularly strong solute-solvent interactions (e.g. intermolecular hydrogen bonds) outweighs the entropic one associated with liberation of solvent molecules, and the resultant crystals contain entrapped solvent molecules. Theoretical aspects of pseudopolymorphism have not been addressed to any great extent despite the practical importance of these species. A recent survey of documented crystal structures of organic compounds indicates that 15 percent of them contain included solvent molecules.

Types of Polymorphic Transformation

Phase transformations are driven by the tendency for minimization of the Gibbs free energy of the system. In the absence of a liquid phase, the transformation of one polymorph to another of lower Gibbs free energy is possible in principle, but such a process is generally very slow due to the high activation energy associated with nucleation and growth of a new polymorph within the solid matrix of the old one.

The presence of a liquid phase can significantly reduce the activation energy for transformation. Melt-mediated and solution-mediated phase transformations are thus common. In the former, following the melting of a metastable polymorph, the stable polymorph crystallizes (Figure 2, monotropic case, applies here). Solution-mediated polymorphic transformations have received much attention because of their practical importance. Here, a stable solid phase crystallizes from a solution which originally contained a metastable phase, mass transfer being effected through the solution medium. The rate of such a transformation depends on several factors, the most important of which are the difference in solubility of the two polymorphs, the nature of the solvent, temperature and the rate of agitation of the solution. Kinetically, this process has been satisfactorily modelled in terms of dissolution of the more soluble metastable phase (characterized by k_D , the rate constant for dissolution), and crystallization and growth of the stable, less soluble polymorph (rate constant k_G). Experimentally, k_D and k_G are determined from the time-dependence of the supersaturation with respect to the stable phase. Hence, the kinetics of transformation can be either growth-limited or

Figure 5 Numerical simulation of the supersaturation-time profiles as a function of the relative rates of dissolution and crystallization during a solution-mediated transformation. Generated from a kinetic model developed by Cardew PT and Davey RJ, (1985) *Proceedings of the Royal Society of London*, A398: 415. (Reproduced with permission from Rodríguez-Hornedo N and Murphy D (1999) *J. Pharm. Sci.* 88: 651. Copyright American Chemical Society and American Pharmaceutical Association.)

dissolution-limited depending on whether the ratio k_D/k_G is large or small. In **Figure 5**, theoretical supersaturation profiles for these extreme cases are compared with the case where the rate constants are equal.

Structural Aspects

The various polymorphs of an organic compound (e.g. those shown schematically in **Figure 1(A)–(C)**), are characterized by different sets of intermolecular interactions (e.g. van der Waals forces, hydrogen bonding, $X-H \cdots \pi$ interactions, where $X = C, N, O$ typically). For molecules containing hydrogen bond donor and acceptor groups, the incidence of polymorphism generally increases owing to the variety of ways in which such molecules can self-

assemble to form supramolecular arrays. **Figure 6** shows portions of the crystal structures of two polymorphs of the drug paracetamol. Despite similar molecular conformations, the intermolecular relationships differ very significantly as a result of the different hydrogen bonding arrangements adopted. Ultimately, it is these features which determine all the observed differences in the physical properties of these polymorphic forms.

Prediction of the crystal structure (or rather, of the family of possible polymorphic structures) of an organic compound from a knowledge of the molecular structure alone is considered a highly desirable goal, but the current state of knowledge of the nature of intermolecular interactions generally prevents its achievement. As to prediction of the outcome of polymorphic crystallization, it would be necessary to invoke additional considerations of thermodynamic, kinetic and solvent effects. These problems are currently being addressed by computational methods with moderate success.

Practical Detection and Analysis of Polymorphs and Pseudopolymorphs

For industrial crystallization, analytical techniques are required for identification of individual polymorphs, quantification of polymorphic mixtures and detection and analysis of pseudopolymorphs. As shown in **Table 1** (which is not exhaustive), many techniques may be used to distinguish polymorphs and to analyse pseudopolymorphs. The primary method is X-ray diffraction, since each crystal structure yields a unique X-ray pattern. As an example, **Figure 7** shows the distinctive powder X-ray diffraction (PXRD) patterns obtained for the monoclinic and orthorhombic polymorphs of a drug substance.

Figure 6 Representative portions of the crystal structures of the monoclinic (left) and orthorhombic (right) polymorphs of paracetamol.

Table 1 Analytical methods suitable for the study of polymorphism and pseudopolymorphism

Analytical method	Principal application for polymorphs and pseudopolymorphs
Elemental analysis	Polymorphs and pseudopolymorphs readily distinguishable due to different chemical compositions
Microscopy	Observation of extinction directions; measurement of refractive indices; determination of optical character (uniaxiality/biaxiality); determination of crystal system
Thermomicroscopy	Visual identification and temperature measurement of desolvation (pseudopolymorphs), polymorphic phase changes, fusion, sublimation, chemical decomposition
Thermogravimetric analysis (TGA)	Measurement of desolvation weight loss (pseudopolymorphs) permitting stoichiometry determination
Differential scanning calorimetry (DSC)	Identification of endothermic events (desolvation, some phase transitions, fusion) and exothermic events (some phase transitions, chemical decomposition)
Infrared spectroscopy	Polymorph identification; detection of included solvents in pseudopolymorphs
Raman spectroscopy	Polymorph identification (complementary to IR)
Powder X-ray diffraction	Primary method for identification of polymorphs and pseudopolymorphs
Single crystal X-ray or neutron diffraction	Complete structural elucidation of polymorphs and pseudopolymorphs
NMR (solution)	Detection of pseudopolymorphs from appearance of peaks due to both parent compound and solvent
NMR (solid state)	Identification of polymorphs and pseudopolymorphs
Solubility measurements	Determination of enthalpies of solution and polymorphic transition temperatures

Detection of more than one polymorph in an industrial crystallization batch may be achieved using this technique since the PXRD patterns are additive. Levels of an adulterating polymorph down to a few percent are detectable. (Near-IR spectroscopy can be equally sensitive in this regard).

When suitable single crystals of the individual polymorphs of a compound can be isolated, complete structural elucidation of each species by X-ray methods is usually possible and highly desirable (cf. Figure 6). The information derived contains all intramolecular parameters (bond lengths, bond angles, conformational parameters) as well as those asso-

ciated with the crystal packing (intermolecular van der Waals contacts and hydrogen bonding) characteristic of each polymorph. These structural parameters can be used to interpret data obtained from other methods. A typical example would be the observation of unequal C=O bond lengths in the molecules of a dimorphic pair, which would account for differences observed in $\nu_{\text{C=O}}$ IR data. For pseudopolymorphs, the observed topology of solvent inclusion (e.g. location within channels, isolated cavities, or layers) and the nature of 'host-guest' hydrogen bonding may be used to explain differences in crystal solvent volatility observed by thermal methods such as DSC. Thus, a knowledge of the crystal structure of each polymorph and pseudopolymorph of a given compound represents a robust foundation for interpretation of many other physicochemical data.

Another major advantage of complete structural elucidation of a polymorph or pseudopolymorph is that the refined parameters may be used to compute an idealized powder XRD pattern for that phase. Such a pattern is invaluable as a primary reference for future identification of that species and for monitoring the purity of the material experimentally during industrial processing.

Implications of Polymorphism and Control of Polymorphic Crystallization

Since the Gibbs free energy differences between polymorphs of the same substance are small (typically 2–3 kJ mol⁻¹), even minor changes in crystallization conditions (intentional or otherwise) can lead to the

precipitation of an undesired polymorph or to mixtures of polymorphs. Hence practical difficulties associated with polymorphism manifest themselves prominently in areas where the same compounds undergo repeated crystallization. One notable example is the pharmaceutical industry, where polymorphism and pseudopolymorphism of active agents used in solid dosage forms may have a very significant effect on the efficacy and quality of the formulation. In particular, since different polymorphs of a drug may have different solubilities and different dissolution rates, use of the inappropriate polymorph in a formulation will compromise the bioavailability of the drug. Other problems which could arise include: (a) use of a thermodynamically unstable polymorph which subsequently undergoes spontaneous transformation into a more stable polymorph, with consequent reduction in bioavailability; (b) solvent-mediated conversion of a drug in a suspension resulting in the slow precipitation of an insoluble drug pseudopolymorph (e.g. a hydrate), again leading to reduction in the concentration of therapeutically active material; (c) transformation of the original polymorph to an undesired one induced by processing conditions, e.g. heating, compression, grinding; (d) precipitation of the drug hydrate instead of the desired anhydrous species due to traces of water in the organic crystallizing solvent. Since reproducible behaviour of the dosage form is of paramount importance, pharmaceutical scientists recognize the necessity for a thorough investigation of the polymorphic and pseudopolymorphic behaviour of a drug during its development in order to avert problems of the type described above. Analogous problems, seriously compromising product performance, occur in other industries. Very detailed documentation of crystallization procedures listing all possible parameters is therefore essential in attempting to ensure reproducible outcomes.

Polymorphism can affect other important technological properties such as tablet compaction. In the case of paracetamol (**Figure 6**), the crystal structure of the monoclinic polymorph has a complex three-dimensional hydrogen bonding network which is not conducive to plastic deformation during pressurization. The crystals consequently resist direct compression during tableting. The facile direct compressibility of the orthorhombic polymorph is attributed to the presence of slip planes in the crystal structure which separate the planes of hydrogen bonded molecules (**Figure 6**), rendering this the industrially desired form of the drug.

In the development of solid-state devices, target species displaying second-harmonic generation are crystallographically non-centrosymmetric polymorphs; their selective crystallization, in preference

to inactive centrosymmetric polymorphs of the same compound, is therefore a goal of crystal engineering. Amino acid crystallization is another area affected by polymorphism. For example, precipitation of the α - rather than the β -polymorph of L-glutamic acid is preferred in industry since the former yields a higher solid-liquid separation efficiency.

The above examples highlight the necessity for controlling crystallization mechanisms to ensure precipitation of the desired polymorph. In addition to the computational studies referred to earlier, there are several experimental approaches to this problem (other than solvent-selective polymorphic crystallization), all of which depend on detailed structural knowledge of the stable and metastable polymorphs of the material in question as a basis for understanding the relationship between molecular interactions in the crystallization medium and the supramolecular structures of the polymorphs that might ensue.

Selective crystallization of metastable polymorphs has been achieved by adding inhibitors which retard the growth of the stable polymorph. Inhibitor design is based on identification of the fastest growing crystal faces of the stable polymorph and tailor-making a substrate which will be incorporated along the direction of fastest growth, thereby blocking crystal development. Polymeric inhibitors have been used to control polymorphism in induced enantiomeric resolution of racemates. Essential to these approaches is detailed knowledge of the relationship between crystal morphology and internal structure and this information can usually be obtained only by X-ray diffraction methods.

Another approach to controlling crystallization is based on the knowledge that the molecular topology of a substrate can affect polymorph selectivity and that such heterogeneous nucleation is energetically more favourable than homogeneous nucleation. The mechanism of ledge-directed epitaxy (LDE), illustrated in **Figure 8**, utilizes these principles. Here, a selected substrate, with surface ledges characterized by θ_{sub} , directs the preferred crystallization of that polymorph exclusively whose prenucleation aggregate has a matching dihedral angle θ_{agg} between close-packed crystal planes. A metastable polymorph with θ_{agg} matching θ_{sub} can thus be induced to crystallize in preference to a stable polymorph for which this geometrical condition is not met.

Future Developments

The renewed vigour with which polymorphism as a phenomenon is currently being investigated is motivated by the demand for reliable methods of reproducible crystallization of specific polymorphs of

Figure 8 Schematic representation of LDE on a single-crystal substrate and the role of LDE in selective nucleation of polymorphs. Symbols are defined in the original reference. (Reproduced with permission from Bonafede SJ and Ward MD (1995) *Journal of the American Chemical Society* 117: 7853, Copyright American Chemical Society.)

industrially important compounds. In the case of pharmaceuticals, further motivation comes from drug-regulatory bodies (e.g. the FDA) which require details of crystallization procedures for specific drug polymorphs and pseudopolymorphs. It is vital that theoretical development of the subject of polymorphism continues to keep pace with these demands. Computational and experimental techniques, which have during the last decade led to substantial advances in the understanding of the primary event in the crystallization process, namely nucleation, are expected to improve in terms of the complexity of the models employed and in the systems investigated. The strategy of 'rational crystal seeding' epitomized by the LDE technique is likely to be applied more widely to the control of polymorphic crystallization. A consequent growth is expected in the number of reports documenting successful isolation of specific polymorphs utilizing approaches based on deliberate intervention at the nucleation stage. Detailed structural elucidation of metastable polymorphs and microcrystalline polymorphs will be facilitated by the combined use of methods such as computational crystal structure prediction, solid state NMR, high-resolution X-ray and neutron powder diffraction, and single crystal X-ray methods employing synchrotron radiation sources. Accompanying the demand for isolation of particular polymorphs, methods for more rapid analysis and quantification will be needed to satisfy both production and legal requirements. An increase in the number and types of on-line systems for continuous monitoring of polymorphic purity in the industrial environment is also envisaged.

Zone Refining

C.-D. Ho and H.-M. Yeh, Tamkang University, Taipei, Taiwan, ROC

Copyright © 2000 Academic Press

Introduction

Zone refining is a powerful tool for applying coupled melting and freezing operations for manipulating impurities in crystals, as well as for separating liquid or solid mixtures. It was first used to purify germanium in 1952. Zone refining combines the well-known fact that a freezing crystal differs in composition from its corresponding liquid phase, so that passing a short heater along a solid ingot leads to a purification of the ingot. For improving the separation efficiency and reducing time, a series of narrow heaters moving slowly over a solid ingot can be used in multi-pass zone refining.

Several mathematical models have been presented for modelling multi-pass zone refining processes when zone length affects the separation efficiency. Furthermore, variable cross-sectional area ingots with specified volumes have been introduced to improve the separation efficiency. Analogue simulators were used to simulate zone refining by means of a single mathematical equation that expresses solute concentration as a function of distance for any initial distribution of solute and any number of passes through an ingot of a specified length. These simulators include liquid mechanical and electrical analogue simulators. Thousands of significant papers devoted entirely or largely to some aspect of application of zone refining have appeared in the last two decades. For instance, silicon-on-insulator (SOI) films, and semiconducting and superconducting materials were prepared by zone refining operations.

Separation Theory in Multi-pass Operation

Eqn (1) can be derived by taking the mass balance within the moving zone ABCD or A'B'C'D' as

shown in **Figure 1**. It is based on the following assumptions: (a) constant distribution coefficient; (b) uniform composition and no diffusion in the molten zone; (c) no change in density during melting and freezing; (d) a constant cross-sectional area for the ingot.

$$\frac{d\bar{C}_n(Z)}{dZ} + \frac{\left(\frac{dY_n(Z)}{dZ} + k\right)}{Y_n(Z)} \bar{C}_n(Z) = \frac{k\bar{C}_{n-1}[Z + Y_n(Z)]}{Y_n(Z)} \left(1 + \frac{dY_n(Z)}{dZ}\right), \quad 0 \leq Z \leq 1 - Y_n(Z) \quad [1]$$

$$\frac{d\bar{C}_n(Z)}{dZ} + \frac{\left(\frac{dY_n(Z)}{dZ} + k\right)}{Y_n(Z)} \bar{C}_n(Z) = 0, \quad 1 - Y_n(Z) \leq Z \leq 1 \quad [2]$$

and the boundary conditions of eqns (1) and (2) become:

$$\text{at } Z = 0, \quad \bar{C}_n = \frac{k}{Y_n(0)} \int_0^{Y_n(0)} \bar{C}_{n-1}(Z) dZ \quad [3]$$

$$\text{at } Z = 1 - Y_n(Z),$$

$$\bar{C}_n = \frac{k}{Y_n(Z)} \left[1 - \int_0^{1-Y_n(Z)} \bar{C}_n(Z) dZ \right] \quad [4]$$

in which:

$$\bar{C}_n(Z) = C_n(x)/C_0 \quad [5]$$

$$Y_n(Z) = l_n(x)/L \quad [6]$$

$$Z = x/L \quad [7]$$

Figure 1 Schematic diagram of zone-refining operation.

The initial solute concentration of the ingot, C_0 , is uniform, the amount of solute, $W_{n,i}$, either transporting away from ($k < 1$), or into ($k > 1$) the i th section after the n th pass, can be calculated by:

$$W_{n,i} = \int_{x_i}^{x_{i+1}} \|C_0 - C_n(x)\| A dx \quad [8]$$

Since the original amount of solute in the ingot is $W_0 = ALC_0$, where A is the cross-sectional area of the ingot, the fraction of solute removed, $f_{n,i}(Y_{n,i}(Z))$, in each section after n passes, is expressed as:

$$f_{n,i}(Y_{n,i}(Z)) = \frac{W_{n,i}}{W_0} = \frac{\int_{Z_i}^{Z_{i+1}} \|1 - \bar{C}_n(Z)\| dZ}{\int_{Z_i}^{Z_{i+1}} \|1 - \bar{C}_n(Z)\| dZ} \quad [9]$$

Once the values of $f_{n,i}(Y_{n,i}(Z))$, $i = 1, 2, \dots, I$ for each section are known, the overall amount of solute removed $F_n(Y_n(Z))$ can be obtained by summing up these values as:

$$F_n(Y_n(Z)) = \sum_{i=1}^I f_{n,i} = \sum_{i=1}^M f_{n,i} = \frac{1}{2} \sum_{i=1}^M f_{n,i} \quad [10]$$

where x_I is the place where $C_n(x) = C_0$ or $\bar{C}_n(Z) = 1$.

Normal Freezing

The optimal zone length Y_1^* for maximum $F_q(Y_1)$ is obtained by solving the equation, $dF_1(Y_1)/dY_1 = 0$, with the use of eqns (9) and (10), since $dF_1(Y_1)/dY_1$ is less than zero for $k < 1$ and $dF_1(Y_1)/dY_1$ is larger than zero for $k > 1$. In order to meet both requirements, therefore, Y_1 must be as large as possible, i.e. normal freezing for all values of the distribution coefficient. Accordingly, the optimal zone length for the first pass is:

$$l_1 = L \quad \text{or} \quad Y_1^* = 1 \quad [11]$$

Varying Optimal Zone Length in Each Pass

The optimal variable zone length $Y_{n,i}^*(Z)$, the corresponding concentration distribution $\bar{C}_n^*(Z)$ and the fractions of solute removal for each section, $f_{n,i}(Y_{n,i}(Z))$, were determined numerically for different values of k with M sections. After the optimal zone length $Y_{n,i}^*(Z)$ for a maximum solute removal $f_{n,i}(Y_{n,i}(Z))$ in each section were achieved, the maximum $F_n(Y_{n,i}^*(Z))$ as well as the corresponding best function of the optimal variable zone length, $Y_n^*(Z)$, were calculated from eqn (10). The optimal functions of variable zone length for up to ten passes are presented graphically in Figure 2.

Constant Optimal Zone Length in All Passes

For constant zone length $Y_{1 \rightarrow n}$ in all passes, $dY_{1 \rightarrow n}/dZ = 0$ and $Y_1 = Y_2 = \dots = Y_n$. In this case, eqns (1)–(7) still apply with $Y_n(Z)$ substituted by $Y_{1 \rightarrow n}$. The optimal zone lengths $Y_{1 \rightarrow n}^*$ for maximum solute removal $F_n(Y_{1 \rightarrow n}^*)$ in n -passes were obtained as follows. First, $\bar{C}_n(Z, Y_{1 \rightarrow n})$ was obtained from eqns (1) and (2) numerically with M sections and with the use of eqns (3) and (4) as well as the given value of $Y_{1 \rightarrow n}$. $F_n(Y_{1 \rightarrow n})$ was then calculated from eqns (9) and (10) and finally, $Y_{1 \rightarrow n}^*$ was obtained from the requirement, $dF_n(Y_{1 \rightarrow n})/dY_{1 \rightarrow n} = 0$.

The optimal values of $Y_{1 \rightarrow n}^*$ are shown in Figure 3 as a function of k with pass number n .

Constant Optimum Zone Length in Each Pass

For this case, we have $dY_n/dZ = 0$ but $Y_{n-1} \neq Y_n$. Eqns (1)–(7) are applicable if $Y_n(Z)$ is substituted by Y_n . The optimal zone lengths Y_n^* for each pass in n -passes were obtained by following the same calculation procedure described in previous sections. The results are shown in Figure 4.

Figure 2 Numerical values of the optimal variable zone length for each pass.

Separation Theory in Analogue Simulators

Zone Refining Simulator for $k < 1$

Zone refining region, $0 \leq x \leq (L - l)$ Figure 5 shows a zone refining simulator for $k < 1$. The ingot is operated by an array of vertical tubes, such as

burettes, of equal internal area a , each with a stopcock, connected in parallel to a common horizontal tube leading to the zone tube. The solute concentration at any point is represented by the height of the liquid level in the tube. Initially, the zone tube is emptied and ingot tubes are filled to height h_0 . The number of open tubes, m , corresponds to the zone length.

Figure 3 Numerical values of the constant optimum zone length for all passes.

Figure 4 Numerical values of the constant optimal zone length for each pass.

The area a_z of the zone tube determines the value of k that is operated, in accordance with:

$$a_z = \frac{ma(1-k)}{K} \quad [12]$$

The liquid level in tube i after the n th pass is:

$$h_i^n = \frac{(m-1)ah_{i-1}^n + ah_{m+i-1}^{n-1} + a_z h_{i-1}^n}{ma + a_z}, \quad i = 1, \dots, N-m \quad [13]$$

It can be seen that the horizontal tube in conjunction with the zone tube performs the essential operations of a travelling molten zone: namely, taking in solute at the leading end; remixing it with the solute in the zone; and freezing out. At the trailing end, a solute concentration is k times that in the zone. In the analogue simulator, as the molten zone advances, it opens the next tube in line, produces the same liquid height in the zone tube and the empty tube connected to it, and then leaves this height in the closed off tube.

Figure 5 Hand-operated liquid-level zone refining simulator for $k < 1$.

DISTILLATION

Azeotropic Distillation

Introduction

An azeotrope occurs when the composition of a vapour in equilibrium with a liquid mixture has the same composition as the liquid. Azeotropic distillation takes advantage of azeotropes that form naturally between many components. Azeotropic distillation involves the formation of an azeotrope, or the use of an existing azeotrope, to effect a desired separation.

For almost 100 years the existence of naturally occurring azeotropes has been used to purify chemicals. In 1902, Young reported using benzene as an azeotropic agent to dehydrate ethanol. This first industrial application was in a batch mode and therefore not conducive to widespread commercial use. Twenty years elapsed before a continuous commercial process was developed. In 1923, Backus, Keyes and Stevens of the United States, and Guinot of France developed continuous azeotropic distillation processes for the dehydration of ethanol. As with Young's batch process, the continuous processes relied upon the ethanol–benzene–water ternary azeotropic mixture for dehydrating ethanol. From that time, azeotropic distillation processes have grown to become an indispensable tool in today's industries.

Desirable properties for an azeotropic entrainer are:

1. Heterogeneous azeotrope for ease of entrainer recovery
2. Commercially available and inexpensive
3. Nontoxic
4. Chemically stable
5. Noncorrosive
6. Low latent heat of vaporization
7. Low viscosity to provide high tray efficiencies
8. Low freezing point to allow ease of handling and storage

Azeotropic distillation is an essential unit operation in today's processes. Applications using azeotropic distillation are readily apparent in the chemical process industry (CPI), speciality chemicals and food industries. Applications from various industries are listed in **Table 1**.

The main advantages of azeotropic distillation are in allowing the separation of chemicals that cannot feasibly be separated by conventional distillation, such as systems containing azeotropes or pinch points, and improving the economics of the separation by saving energy and increasing recovery. The main disadvantages of azeotropic distillation are the larger diameter column required to allow for increased vapour volume due to the azeotropic agent, and an increase in control complications compared with simple distillation.

A minimum-boiling azeotrope can be formed by the introduction of an azeotrope-forming compound (entrainer) to an existing azeotropic mixture or close-boiling mixture for which separation by

Table 1 Industrial applications of azeotropic distillation

Industry	Application	Separation involved	Typical entrainers
CPI	Acetic acid recovery or purification	Acetic acid/water	Ethyl acetate, butyl acetate

Food	Production of L-aspartyl-L-phenylalanine methyl ester (sweetener)	Acetic acid/toluene azeotrope	Water

CPI, chemical process industry.

conventional distillation is not feasible. One example is alcohol dehydration. Ethanol and water form a minimum-boiling azeotrope with ethanol as the major component and therefore ethanol cannot be completely dehydrated by conventional distillation. Benzene forms a ternary azeotrope with ethanol and water, which boils at a lower temperature and will therefore remove the water (with some ethanol) overhead, leaving dry ethanol as a bottoms product.

In some cases, an azeotrope that exists within the system can be used advantageously to purify a compound, as in the production of esters. The esterification of alcohols involves a reversible reaction. Being equilibrium limited, the reaction will not go to completion in the presence of the product. If one of the products is removed (in this case water) utilizing the water/alcohol azeotrope (almost all alcohols from C₂ to C₂₀ form azeotropes with water) the reaction is driven in favour of the ester product. A comprehensive list of many azeotrope-forming compounds can be found in the publication *Azeotropic Data III*, by Horsely (see Further Reading section).

Relative volatility is a comparison of the volatilities of the components in the mixture. When the compositions of the vapour and liquid phases are the same, the volatilities of the components are the same and the relative volatility is equal to 1. The further the relative volatility is away from 1, the easier it is to separate the components of the mixture. Figure 1 illustrates the number of theoretical stages required to separate two components to 99% purity compared with the relative volatility of the mixture. As can be

seen, the number of trays required asymptotically approaches infinity and the separation becomes impossible as the relative volatility approaches unity. A relative volatility close to unity could indicate the presence of a pinch point. It is technically feasible to separate components that form a pinch point, but often not economic due to the large number of stages required to effect the separation.

Homogeneous azeotropes exist when the vapour is in equilibrium with a single liquid phase. In a homogeneous azeotropic system, the entrainer must be recovered by additional fractionation or extraction. Figure 2 illustrates the homogeneous azeotropic

Figure 1 Relative volatility versus theoretical stages required to separate two components to 99% purity.

Figure 2 Typical homogeneous azeotropic distillation system utilizing a liquid-liquid extraction (LLE) column to separate the overhead product from the entrainer.

distillation system. Heterogeneous azeotropes exist when the vapour is in equilibrium with two liquid phases. Heterogeneous azeotropic distillation is widely used for the separation of azeotropic or close-boiling mixtures by forming a minimum-boiling azeotrope and taking advantage of the liquid-liquid immiscibility to recover the entrainer. **Figure 3** illustrates a typical azeotropic distillation system of a heterogeneous azeotrope.

Acetic Acid Recovery

There are many industrial processes where acetic acid and water coexist and must be separated. One such process is the production of terephthalic acid. Terephthalic acid (TA) is a polyester raw material used to produce fibres, films and bottles. Terephthalic acid production is important because of the phenomenal growth of this product in the market. The worldwide purified terephthalic acid (PTA) production is currently 15 million tonnes per year, with a growth rate of 12% per annum expected well into

Figure 3 Typical heterogeneous azeotropic distillation system.

the twenty-first century. Let us examine the operational advantage of using azeotropic distillation in the production of purified terephthalic acid.

The production of PTA includes two main sections, oxidation and purification. Within the oxidation unit, *p*-xylene is catalytically oxidized to produce crude TA. **Figure 4** shows a PTA oxidation section block diagram. Acetic acid is present in the oxidation reactor as a solvent and has also been found to be beneficial in the oxidation reaction itself.

Critical to the efficient and economical operation of a PTA plant is the recovery and recycling of the acetic acid solvent. The acetic acid must be separated from the water that is produced as a product of oxidation. Water and acetic acid exhibit a pinch point at high water concentrations making it very difficult to recover the pure acid. **Figure 5** illustrates the water/acetic acid pinch point on a graph of the fraction of water in liquid phase versus the fraction of water in the vapour phase.

In this process, a clean separation of acetic acid from water is vital. If the acetic acid recycled to the reactor contains too much water, the oxidation reaction will be inhibited, resulting in a decrease in overall yield. If the water being disposed as waste contains acetic acid, the acid must be treated within a wastewater treatment facility. Therefore, any acid losses count against the process economics both as increased make-up solvent required and increased wastewater treatment costs.

The acetic acid recovery unit separates the acetic acid to be recycled to the reactor, from water that can be polished for disposal. A conventional acetic acid recovery unit in a PTA process consists of the low and high pressure absorbers and the acid dehydration column. The low pressure absorber uses water to absorb acetic acid and methyl acetate (reaction by-product) from the TA drier gas. The high pressure absorber uses water to absorb acetic acid and methyl acetate from the reactor off-gas. These streams generally make up 25% of the feed to the dehydrator and contain less than 30% concentration of acetic acid. The remaining feed to the dehydrator column comes

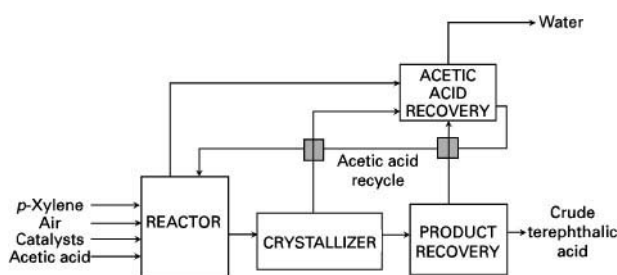

Figure 4 PTA oxidation section block diagram.

Figure 5 Diagram illustrating acetic acid/water pinch point on a graph of the fraction of water in the liquid phase versus the fraction in the vapour phase.

from the crystallizers. **Figure 6** shows a conventional acetic acid recovery unit using azeotropic distillation in a PTA process.

Typically the acetic acid/water separation of the acid recovery unit is accomplished by either conventional distillation or azeotropic distillation. Separation of acetic acid and water by conventional distillation requires a very tall column, containing 70 to 80 trays.

Preferably, the acid dehydration column in the solvent recovery unit can be operated as an azeotropic distillation column. As an example, let us assume the azeotropic agent used is *n*-butyl acetate. *n*-Butyl acetate and water exhibit limited miscibility and therefore form a heterogeneous azeotrope which boils at 90.2°C. *n*-Butyl acetate is added in sufficient quantities to form an azeotrope with all the water being fed

to the dehydration column. The *n*-butyl acetate/water azeotrope can then be distilled as an overhead stream, leaving the pure acetic acid as the bottoms product. The heterogeneous azeotrope forms two phases upon condensation, with the top layer containing almost pure *n*-butyl acetate saturated with water. The bottom phase contains almost pure water saturated with *n*-butyl acetate. The top (entrainer) phase is recycled back to the dehydration column. The bottom phase (aqueous) is fed to a stripping column where the relatively small amount of entrainer is removed as an azeotrope with the overhead back to the dehydration column and water is removed as the bottom product.

The use of azeotropic distillation in the PTA process has economic and environmental advantages over conventional distillation for acetic acid recovery. Due to the lowered heat of vaporization of the azeotrope compared with that of water alone, azeotropic distillation can save one-third the energy of conventional distillation. Since azeotropic distillation results in a cleaner separation, the amount of acetic acid lost in the aqueous discharge can be reduced by almost 40%. **Table 2** shows the substantial advantages of using azeotropic distillation in this commercial application.

Production of PTA is just one illustration of azeotropic distillation being used in the commercial separation of acetic acid and water. Azeotropic distillation is also used in the production of acetic acid. The most popular methods for producing acetic acid are methanol carbonylation, butane or naphtha catalytic liquid-phase oxidation (LPO) and acetaldehyde oxidation. Methanol carbonylation is used for more than 90% of all new acetic acid capacity worldwide. In methanol carbonylation methanol and carbon monoxide are reacted over a rhodium catalyst under gentle operating conditions to produce acetic acid. The reaction produces low boiling by-products which are flash distilled to recover the rhodium catalyst. The remaining acid is dehydrated by azeotropic distillation much the same way as described in the PTA acetic acid recovery unit.

Butane/naphtha catalytic liquid-phase oxidation was once the most favoured method for the production of acetic acid. Along with acetic acid, a host of other components are produced such as

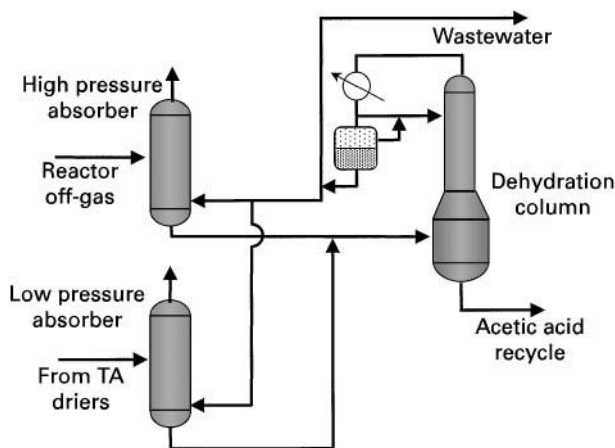

Figure 6 Conventional acetic acid recovery unit using azeotropic distillation in a PTA process.

Table 2 Comparison of distillation methods for PTA production

Parameter	Conventional distillation	Azeotropic distillation

WW = wastewater.

formic, propionic and butyric acids. Azeotropic distillation is used to separate the formic acid and water from the aqueous reactor product.

In acetaldehyde oxidation, ethanol is dehydrogenated oxidatively to acetaldehyde using a silver, brass or bronze catalyst. Acetaldehyde is oxidized in the liquid phase over cobalt and manganese catalysts to produce acetic acid. The final purification process uses ethyl acetate to azeotropically remove formic acid and water. The acetic acid product is removed as a side stream from the azeotropic column.

Alcohol Dehydration

Azeotropic distillation for alcohol dehydration has the longest history of use within the industry. Beginning with the work of Young, who demonstrated the first industrial application, azeotropic distillation is still used today in the production and dehydration of alcohol. Alcohol production is present in the CPI, speciality chemicals and food industries, and although the end use and perhaps the alcohol purity requirements vary, the method of production using azeotropic distillation is similar.

Prior to Young's work, absolute alcohol was prepared by distilling the alcohol with a dehydrating agent such as freshly ignited lime. This method required the major component (alcohol) to be boiled overhead leaving the minor component (water) at the bottom. Young's objective was to find a method of removing the minor component as the overhead product. When two different chemicals are distilled together, often a minimum boiling point occurs where a mixture of the two chemicals will distil off first, with the last portion being the compound in excess. Since ethanol is a hydroxyl compound like water and yet an organic compound, it should exhibit analogies to both water and hydrocarbons. Therefore, ethanol should form azeotropes with water and organic compounds. If an azeotroping agent such as benzene is used (in Young's time benzene and heptane were preferred due to their availability), the fractions would come off as follows: ternary water/benzene/alcohol azeotrope; alcohol and benzene azeotrope; and water and benzene azeotrope. At this point, all the water should be removed, leaving anhydrous alcohol. Young performed his azeotropic dehydration of alcohol by a batch method. While popular for distilling strong spirits, this batch method did not catch on commercially. It was not until Backus *et al.* and Guinot developed continuous azeotropic distillation processes that it became a commercial success.

As an example of an alcohol dehydration process, let us examine ethanol dehydration. Dilute water/

ethanol solutions can be rectified to produce an ethanol-rich stream containing a maximum of about 89.4 mol% ethanol at atmospheric pressure. The introduction of benzene as a heterogeneous azeotropic entrainer to the top of the column, which is fed with an 89.4 mol% aqueous ethanol feed, produces the ternary ethanol/benzene/water azeotrope. This ternary azeotrope boils at 64.9°C and is easily separated from ethanol (b.p. = 78.4°C), which is removed as the bottom product. The ternary ethanol/benzene/water azeotrope forms two liquid phases with the benzene-rich phase fed back to the column. The aqueous phase contains nearly equimolar proportions of ethanol and water which is rectified to produce water as the bottom product and the binary ethanol/water azeotrope as the overhead product. The concentrated ethanol/water azeotropic stream is recycled back to the feed for the dehydration column. **Figure 7** illustrates a typical ethanol dehydration process.

Production of Esters

Esters are produced by reacting alcohols with organic acids. The reaction is reversible and therefore unless one of the products is removed, the ester yield is limited. Assuming the reaction is equilibrium-limited and not rate-limited, higher conversions can be obtained by removing one of the products. For instance, if during the reaction the water is removed, the reaction will be driven by equilibrium to produce more ester product. High purity esters can be produced with azeotropic distillation to simultaneously remove water and alcohol from the esters using aromatic and aliphatic hydrocarbons as entrainers.

Mato Vazquez *et al.* found isobutyl acetate, *n*-butyl acetate and *iso*amyl acetate could be purified using an entrainer such as *n*-heptane, methyl cyclopentane or various other hydrocarbons to simultaneously remove the water and alcohol. The reaction products are fed to an azeotropic column where the entrainer is used to remove the alcohol and water as overhead

Figure 7 Typical ethanol dehydration process using azeotropic distillation.

products. Final purification of the ester product is carried out in a rectification column with only a few stages. The entrainer is recovered using a one-step liquid–liquid extraction (LLE) column with water as the extractant.

Wuest *et al.* found they could prepare ethyl chloroacetate by addition of ethanol to a melt of chloroacetic acid and *p*-toluene sulfonic acid and purify the ester product using azeotropic distillation. The ester and water form a minimum boiling binary azeotrope and therefore affect the ester/alcohol separation. Water and ethyl chloroacetate are removed overhead and the product is decanted. In this manner the ester is practically alcohol-free. This process avoids formation of the ternary ester/alcohol/water azeotropes which are difficult to separate.

Hills *et al.* found that azeotropic distillation is useful in the purification of esters produced using an enzymatic route. For example, isopropyl myristate can be prepared with lipase or immobilized lipase from myristic acid and propane-2-ol. The water produced in the reaction is removed by azeotropic distillation.

Conclusion

For almost 100 years azeotropic distillation has been an essential tool in the separation and purification of many industrial chemicals. There are distinct advantages to using azeotropic distillation, including energy savings, increased recovery and ability to separate components contained in close boiling, pinch point and azeotropic mixtures. Azeotropic distillation will undoubtedly remain a viable alternative for simplifying difficult separations found in industry.

Batch Distillation

M. Barolo, Università di Padova, Padova, Italy

Copyright © 2000 Academic Press

Introduction

The interest in batch distillation has been steadily increasing in the last few years. This is a natural reflection of a change in industrial trends. In fact, the

shift towards the production of high value-added and low volume speciality chemicals and biochemicals has been much more marked in the last decade than in the past. Within firms producing specialized chemicals and biochemicals, batch distillation is a ubiquitous method for separating products from process inventories, for recovering components that are used in one of the process steps (like solvents, for example), and for removing undesired components

from an effluent stream. Examples of industrial applications of batch distillation include: the recovery of chloroform, butanol, water, organic and inorganic acids from process broths in the pharmaceutical industry; the concentration of acetone from dilute aqueous mixtures and the removal of water from butyl alcohol in the fine chemistry industry and the manufacture of alcoholic beverages from fermented mixtures in the food and beverages industry.

The success of batch distillation as a method of separation is undoubtedly due to its flexibility. In fact, a single batch column can separate a multicomponent mixture into several product cuts within a single batch but if the separation were carried out continuously, either a train of columns or a multi-pass operation would be required. Also, whenever completely different mixtures must be processed from day to day, the versatility of a batch column is still unexceeded. These attributes are crucial for responding quickly to a market demand characterized by short product lifetimes and severe specification requirements.

Equipment Arrangements and Process Modelling

Simple Distillation

The simplest batch distillation apparatus is shown in Figure 1. The operation is known as simple distillation or differential distillation. This is the oldest manifestation of distillation itself; it was used by many ancient cultures as a way of producing alcoholic beverages, essential oils and perfumes.

With regard to the separation of a binary mixture, the batch apparatus is run as follows. The pot is continuously heated, so that a vapour rich in the more volatile component is produced, condensed and collected in the external receiver. Indicating with x_B and y the instantaneous mole fractions of the more volatile component in the liquid and vapour phases in equilibrium, and with H_B the molar amount of boiling liquid remaining in the pot, the following material balances hold during any small time interval:

$$dH_V = -dH_B \quad [1]$$

$$y dH_V = -d(H_B x_B) \quad [2]$$

where dH_V is the molar amount of vapour produced during the same time interval. Combining [1] and [2], and integrating from the original feed conditions (H_F moles of boiling liquid of mole fraction z) to the present conditions, leads to the so-called Rayleigh equation:

$$\ln \frac{H_B}{H_F} = \int_z^{x_B} \frac{dx'_B}{y - x'_B} \quad [3]$$

Eqn [3] can be integrated numerically or graphically. It relates the amount of liquid remaining in the pot to the composition of this liquid. The molar amount H_D and average composition \bar{x}_D of the liquid accumulated in the receiver can be determined from the following material balances:

$$H_F = H_B + H_D \quad [4]$$

Figure 1 Apparatus for simple distillation.

and:

$$H_F z = H_B x_B + H_D \bar{x}_D \quad [5]$$

If the system displays a constant relative volatility (α), the integration of eqn [3] can be performed analytically, leading to:

$$\ln \frac{H_B}{H_F} = \ln \frac{1-z}{1-x_B} + \frac{1}{\alpha-1} \ln \frac{x_B(1-z)}{z(1-x_B)} \quad [6]$$

A graphical representation eqn [6] is presented in **Figure 2**. It is shown that, for a given fractional purification x_B/z of the feed, a larger amount of liquid can be recovered at the end of the batch when the feed is leaner in the more volatile component. It is also clear that it is not possible to obtain a finite amount of the pure heavy component, whatever the feed composition.

For a mixture of N_c components, N_c Rayleigh equations of the form [3] can be derived, and an iterative procedure is usually employed in order to determine the composition profile of each component as a function of the amount of liquid remaining in the still. In the case of constant relative volatility mixtures, direct calculation of the composition profiles can be accomplished by defining the amount b_i of the i th component remaining in the pot ($b_i = H_B x_{B,i}$). It can be shown that:

$$\frac{b_i}{f_i} = \left(\frac{b_j}{f_j} \right)^{\alpha_{i,j}} \quad [7]$$

where j is an arbitrarily chosen reference component, $f_i = H_F z_i$, and $\alpha_{i,j}$ is the relative volatility of the i th component with respect to the reference one. From

Figure 2 Simple distillation: fraction of the initial charge recovered after the purification of three different binary feeds from a light impurity.

the definition of b_i , it follows that:

$$x_{B,i} = \frac{b_i}{\sum_{i=1}^{N_c} b_i} \quad [8]$$

Differential distillation is a very simple way of separating a mixture of several components into cuts of different purities, for example for laboratory applications. However, it permits only rough separations, even with large energy consumption (it is a one-theoretical-stage operation). This is the reason why multistaged columns with reflux are employed whenever a sharper separation is needed.

Batch Rectification

A typical batch distillation column (a batch rectifier) is shown in **Figure 3**. The feed mixture is charged to a large reboiler, to which a heating medium (e.g. steam) is also fed. The vapour reaching the top of the column is condensed, and partially returned as reflux. A distillate stream is withdrawn, which sequentially feeds a series of tank receivers. The column may be a staged or a packed one.

Since in practice it is much more frequently requested to operate an existing column rather than to design a new one, only the issues of modelling and operating an existing rectifier will be addressed in the following sections.

Regardless of the operating mode, the column-modelling approaches can be grouped into three main classes: short-cut modelling, approximate modelling and rigorous modelling.

Short-cut models Short-cut models usually assume that the column dynamic behaviour can be approximated as a sequence of steady states (pseudo-steady-state approximation), which in turn is true when the column and reflux drum hold-ups can be neglected compared to that of the reboiler. This assumption allows the short-cut models that have been devised for the design of continuous columns to be employed at every time step in the simulation of batch columns. When binary mixtures are considered, a graphical representation of the process can be obtained by means of classical McCabe–Thiele diagrams. For multicomponent mixtures, a modification of the Fenske–Underwood–Gilliland design approach is often employed for simulating the batch column operation.

The main advantage of these models is their speed of computation; the main limits are their poor accuracy, and the fact that most of them are limited to constant relative volatility mixtures. They are mostly employed in preliminary process design and

Figure 3 Sketch of a batch rectifier.

optimization studies, when a large number of cases need to be evaluated quickly, and a result of limited accuracy is acceptable. Rigorous results can be obtained by the subsequent use of more accurate models.

Approximate models Approximate models are used whenever a more realistic representation of the column dynamics is required. In this case, the tray and reflux drum liquid hold-ups are explicitly taken into account, even though they are usually assumed to be constant throughout the whole operation. Other usual assumptions are: boiling feed, total condensation without subcooling, perfect mixing in all parts, negligible vapour hold-ups, constant boil-up rate, constant molar overflows, ideal tray behaviour and negligible pressure drops and heat losses.

The set of equations usually employed to model a column with a separating capacity of N ideal trays is as follows:

Reboiler

$$\frac{dH_B}{dt} = L - V \quad [9]$$

$$\frac{d(H_B x_{B,j})}{dt} = Lx_{1,j} - Vy_{B,j} \quad j = 1, 2, \dots, Nc - 1 \quad [10]$$

Bottom tray (tray 1)

$$H_1 \frac{dx_{1,j}}{dt} = L(x_{2,j} - x_{1,j}) - V(y_{1,j} - y_{B,j}) \quad j = 1, 2, \dots, Nc - 1 \quad [11]$$

Tray i

$$H_i \frac{dx_{i,j}}{dt} = L(x_{i+1,j} - x_{i,j}) - V(y_{i,j} - y_{i-1,j}) \quad j = 1, 2, \dots, Nc - 1 \quad [12]$$

Top tray (tray N)

$$H_N \frac{dx_{N,j}}{dt} = L(x_{D,j} - x_{N,j}) - V(y_{N,j} - y_{N-1,j}) \quad j = 1, 2, \dots, Nc - 1 \quad [13]$$

Reflux drum

$$\frac{dH_D}{dt} = 0 \quad (V = L + D) \quad [14]$$

$$H_D \frac{dx_{D,j}}{dt} = V(y_{N,j} - x_{D,j}) \quad j = 1, 2, \dots, Nc - 1 \quad [15]$$

Thermodynamic equilibrium in stage i

$$y_{i,j} = K_{i,j} x_{i,j} \quad j = 1, 2, \dots, Nc - 1 \quad [16]$$

Summation constraints

$$x_{i,Nc} = 1 - \sum_{k=1}^{Nc-1} x_{i,k} \quad [17]$$

$$y_{i,Nc} = 1 - \sum_{k=1}^{Nc-1} y_{i,k} \quad [18]$$

In the above equations, H_i , H_D and H_B are the tray, reflux drum and reboiler hold-ups respectively; $x_{i,j}$ is the mole fraction of component j in stage i ; L , V and D are the liquid, vapour and distillate molar flow rates (respectively); $K_{i,j}$ is the vapour/liquid equilibrium ratio of component j in stage i ; and t is the time. Any suitable thermodynamic model can be used for the representation of the equilibrium ratio; deviations from the ideal tray behaviour can be taken into account using the Murphree tray efficiency concept. Due to possible wide ranges in the relative volatilities and/or large differences in tray and reboiler hold-ups, the system of differential equations is frequently stiff. As a starting point for the integration, it is often assumed that the reboiler, reflux drum and all trays are filled with the boiling liquid feed at the beginning of the operation.

Approximate models provide a fairly accurate description of the column dynamics, and are frequently used in process design and process optimization applications.

Rigorous models When a still more accurate description of the process dynamics is needed (for example, when it is required to model accurately the operation of an existing column), a rigorous model should be employed. In this case, almost all of the previous assumptions are relaxed, which considerably increases the computational load. The deter-

mination of the system and equipment parameters (like the Murphree tray efficiency, for example) is done by fitting some of the modelled profiles to actual plant data.

Other Column Arrangements

In the attempt to improve the flexibility of batch distillation operation as a whole, a closer look at alternative column configurations has been undertaken in the last few years. These different kinds of columns have been known since the 1950s, but a thorough understanding of their dynamic behaviour and features has only recently been achieved.

In the batch stripper represented in Figure 4A, the feed is charged to the reflux drum, while multiple cuts are withdrawn from the bottom of the column sequentially. In the middle-vessel batch column (Figure 4B), the feed is charged to an intermediate vessel, and the product/impurity removal is accomplished simultaneously from both the top and the bottom ends. The reboilers of both columns may be considerably smaller than the reboiler of a batch rectifier.

Potential improvements in column productivity, with respect to conventional batch rectifiers, may be very large when using these alternative configurations. However, to date it is not possible to provide general guidelines for determining *a priori* the best column configuration for a certain separation.

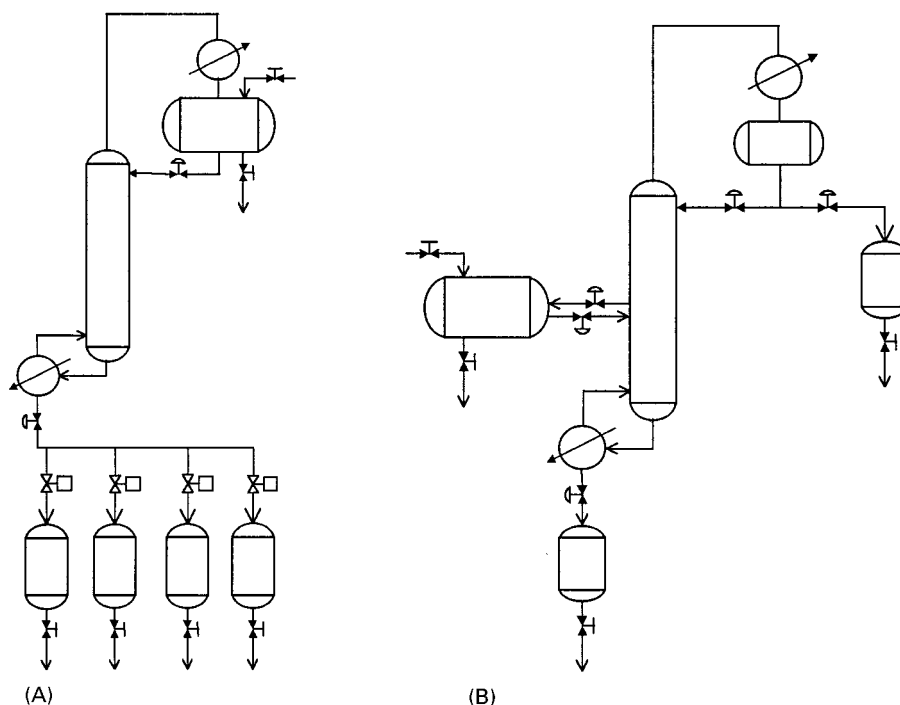

Figure 4 Sketch of (A) a batch stripper and (B) a middle-vessel batch column.

A preliminary simulation with a simplified model (or even with a short-cut one) should be used to assess the most profitable configuration for separating a given feed (amount and composition), subject to the given purity constraints.

Column Operation

The operation of a batch rectifier only will be considered in here. The most popular operating modes are: constant reflux ratio (with variable distillate composition), constant distillate composition (with variable reflux ratio) and total reflux (no product take-off). The former two operations are in fact semi-batch operations; the latter one is truly a batch operation. Operation at optimal reflux ratio should be mentioned too, but – since it is often accomplished through a series of constant reflux ratio sequences – this operating mode will not be considered here. In the following, the components are numbered in order of decreasing ease of separation (i.e. component 1 is the most volatile one, component 2 is the second most volatile, and component N_c is the least volatile).

From a practical point of view, regardless of the operating policy, the operation of a multicomponent column is carried out in three steps: (i) a start-up phase; (ii) a main cut production phase; and (iii) a slop cut removal phase. The last two steps are repeated sequentially. The following actions take place during the start-up phase: the column and receivers are possibly cleaned from the materials processed in the previous batch; cooling of the condenser is started; steam is fed to the reboiler, so that the material to be processed is heated up to its bubble point and starts to vaporize; as soon as the overhead vapour has been condensed and has filled the reflux drum, liquid is returned to the top of the column, and the column is run at total reflux; consequently, the column trays are sequentially filled with liquid.

The start-up procedure is very general, and goes on until either the steady state is approached, or the lighter product purity specification is reached in the reflux drum. The other two phases vary according to the operating policy employed.

Constant Reflux Ratio Operation

In the case of the separation of a binary mixture, a short-cut modelling approach is useful in order to have a graphical representation of the process. In a McCabe–Thiele diagram, at a given value $r = L/D$ of the reflux ratio, the slope of the operating line is fixed during the operation (Figure 5).

Figure 5 Binary batch distillation at constant reflux ratio (three-ideal-stage column).

While the distillation is proceeding, the operating line shifts down along the diagonal line. The mole fraction of the more volatile component in the distillate is continuously decreasing, and, at any instant of time, the reboiler composition is determined by stepping off N stages along the operating/equilibrium lines.

If both the top and the bottom purity specifications (x_D^{spec} and x_B^{spec} , respectively) are assigned, the reflux ratio should be chosen such that the final amount H_B^{final} of bottom product, as calculated through eqns [4] and [5] with $x_B = x_B^{\text{spec}}$ and $\bar{x}_D = x_D^{\text{spec}}$, is the same as the amount calculated by means of the Rayleigh equation:

$$\ln \frac{H_B^{\text{final}}}{H_F} = \int_{x_B^{\text{spec}}}^{x_D^{\text{spec}}} \frac{dx_B}{x_D - x_B} \quad [19]$$

The integral of eqn [19] can be evaluated numerically or graphically. The total amount Q_r of energy to be supplied at the reboiler is given by:

$$Q_r = \lambda(r + 1)H_D^{\text{final}} \quad [20]$$

where λ is the molar latent heat of vaporization of the mixture, and H_D^{final} is the final amount of distillate product collected.

For a multicomponent mixture, after starting up the column, the product removal is started at a constant and finite reflux ratio, and it continues until the average composition of the accumulated product (product 1) falls below the specification. At this point (called the cut-off point), the distillate composition is

neither sufficiently rich in component 1 to allow further accumulation of product 1, nor is it sufficiently rich in component 2 to allow beginning the withdrawal of product 2. Therefore, the distillate stream is diverted to another tank, and the collection of slop cut 1 is started. When the concentration of component 2 in the reflux drum meets the second product's specification, the distillate stream is diverted to a third receiver, and the accumulation of product 2 is initiated. The operation proceeds this way until all the products but the heaviest have been collected in the receivers. The heaviest product (product N_c) is recovered in the reboiler at the end of the operation. Therefore, at the end of the operation N_c main cuts (products) and at most $N_c - 1$ slop cuts are obtained. The slop cuts need to be reprocessed in subsequent batches.

It should be noted that, unless this issue has been addressed at the column design stage, the whole tray

hold-up drains to the reboiler when the steam supply is stopped. This must be taken into account when estimating online the final reboiler composition in order to detect the time when the distillation should be interrupted.

The plot of a typical evolution of the profiles of the average product composition, product amount and instantaneous distillate composition for the separation of a nonazeotropic ternary mixture at constant reflux ratio is shown in Figure 6. The profiles were determined with the approximate model described previously, and a constant relative volatility mixture was considered.

The dynamic behaviour of the column is characterized by a 'front' of each component sequentially moving from the bottom to the top of the column. If the column has enough stages, the top trays virtually separate a binary mixture made of the current most volatile component and its adjacent

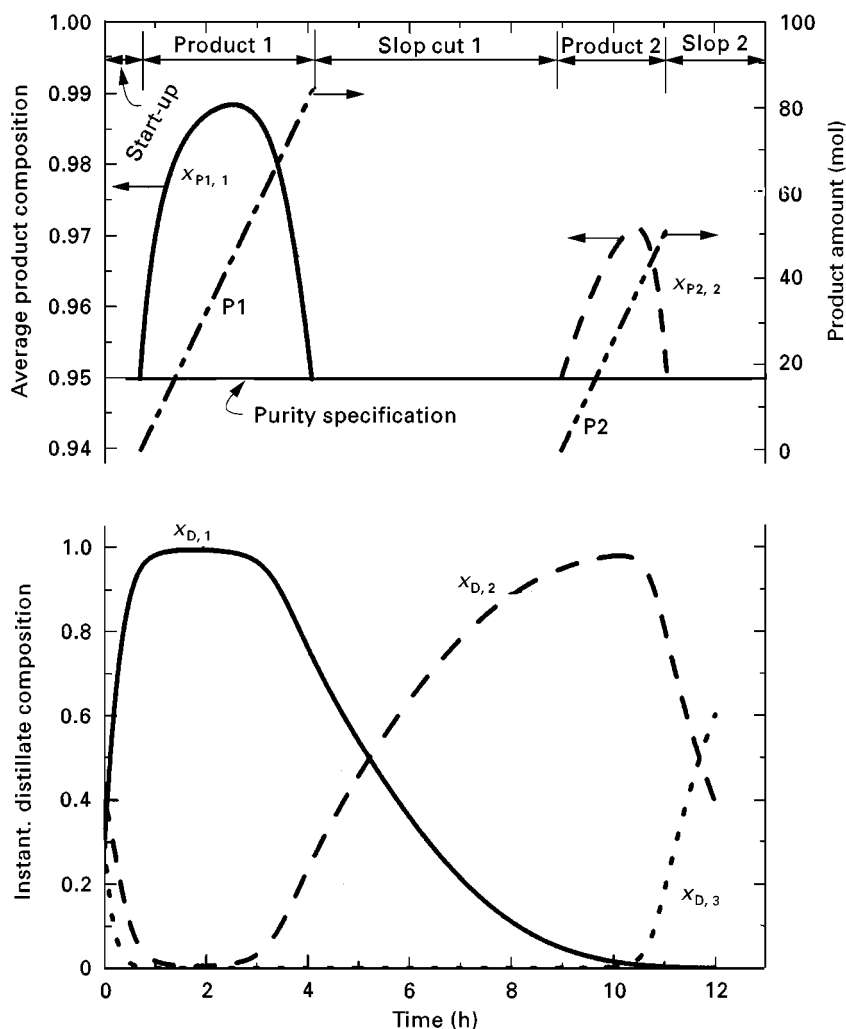

Figure 6 Typical evolution of the profiles of the average product composition, product amount and instantaneous distillate composition for an ideal ternary mixture under constant reflux ratio operation.

component in the scale of relative volatilities. This may prove advantageous for the control of the operation.

Operation at constant reflux ratio is the most popular in industry, because it is very easy to accomplish. However, some considerations deserve attention at this point. In order to implement this operating policy practically, a measure of the distillate and reboiler compositions should be available online, which is not usually the case. Therefore, the product composition needs to be inferred from secondary measurements, which should be available online quickly and at a low cost (like temperature and flow rates, for example). Also, operating the column at a constant reboiler duty is often easier than operating it at constant vapour boil-up, as was done in the previous numerical example. Finally, it should be noted that the column pressure may be decreased during the batch in order to improve the ease of separation of the less volatile components.

Constant Distillate Composition Operation

For the separation of a binary mixture under the quasi-steady-state assumption, a quick glance at the process can be obtained again by using a McCabe–Thiele representation, as shown in Figure 7.

In order to get the desired specification x_D^{spec} from the very beginning of the operation, the initial value of the reflux ratio must be such that the feed composition z is exactly obtained in the still when stepping off N stages from x_D^{spec} . Then, the reflux ratio (hence, the

slope of the operating line) is continuously increased during the batch in order to keep the distillate composition on specification. The operation is interrupted when either the reboiler composition has reached the desired composition, or the reflux ratio is so high that continuing the operation would be uneconomical (or even impossible, in an actual column).

The determination of the total amount of energy that needs to be supplied to the still is obtained by the following equation:

$$Q_r = \lambda \int_0^{H_D^{\text{final}}} (r + 1) dH_D \quad [21]$$

whose integration requires knowing r as a function of H_D . By combining eqns [4] and [5], with $\bar{x}_D = x_D^{\text{spec}}$, it is found that:

$$H_D = H_F \frac{z - x_B}{x_D^{\text{spec}} - x_B} \quad [22]$$

which enables relating the instantaneous reboiler composition (x_B) to the amount of product (H_D) collected up to the same instant. Therefore, since the reflux ratio can be related to x_B at any instant of time, eqn [21] can be easily integrated.

In a multicomponent separation, product 1 is collected until the reflux ratio reaches the prespecified maximum value. Then, the reflux rate is decreased in order to allow a quick removal of the remaining traces of the most volatile component (these traces are accumulated in slop cut 1). At the same time, this enables the front of the second lightest component to build up in the column so that, when the reflux drum composition meets the specification for product 2, the accumulation of this product is started. The production phase and the slop removal phase are then repeated sequentially; product Nc is eventually recovered from the reboiler.

Since operation at constant distillate composition is inherently a feedback operation, some kind of feedback from the plant is needed in order to be able to determine the correct value of the reflux ratio at any instant. When the distillate composition measurement is not available online, the most convenient feedback signal that can be used is a pilot tray temperature measurement. This strategy is similar to the one applied for one-point composition control in continuous columns. In principle, temperature control should be applied to binary mixtures only, but it can be extended to multicomponent mixtures, provided that the column has enough trays. Note that, similarly to continuous distillation, the measuring element must be placed somewhat down from the top of the column in order to ensure sensitivity of the temperature

Figure 7 Binary batch distillation at constant distillate composition (three-ideal-stage column).

response to changes in the distillate composition. Therefore, if good control at a constant set point is provided, the product purity usually increases while this product is being removed from the column. This is because the separating capacity of the column increases during the batch, due to the increase of the reflux rate.

From a practical point of view, this kind of operation is harder to implement than constant reflux ratio, even if a measure or an estimate of the distillate composition is available online. Because the dynamics of the process may change significantly as the batch proceeds, conventional proportional plus integral controllers often prove to be inadequate for tight composition control. Care should be taken when the reflux rate increases widely, because the liquid loading to the column might increase to a point that flooding conditions are reached.

Total Reflux Operation

This operation is the best suited for binary mixtures, whose components should be recovered at a relatively high degree of purity. The feed charge H_F is split between the reflux drum (H_D kmol) and the reboiler (H_B kmol), and the column is operated at total reflux for the whole duration of the batch. Under the assumptions of quasi-steady-state operation and constant relative volatility, the operation can be analysed easily. For a given pair of product specifications, the minimum number N_{\min} of theoretical stages necessary in order to achieve the desired separation can be determined from the Fenske

equation:

$$N_{\min} = \frac{1}{\ln \alpha} \ln \frac{x_D^{\text{spec}}(1 - x_B^{\text{spec}})}{x_B^{\text{spec}}(1 - x_D^{\text{spec}})} \quad [23]$$

If the operation is feasible in the available column, the requested top and bottom hold-ups are calculated immediately by eqns [4] and [5], with $x_B = x_B^{\text{spec}}$ and $\bar{x}_D = x_D^{\text{spec}}$.

At any time t , the operating line is parallel to the diagonal line in a McCabe–Thiele diagram (Figure 8), and moves towards the diagonal as time progresses according to the following dynamics:

$$V(y - x) = H_D \frac{dx_D}{dt} \quad [24]$$

or:

$$V(y - x) = -H_B \frac{dx_B}{dt} \quad [25]$$

Since, at time t , the following material balance holds true:

$$\frac{x_D - z}{z - x_B} = \frac{H_B}{H_D} \quad [26]$$

the reflux drum and reboiler compositions at the same time instant can be determined by using the auxiliary line \overline{FQ} , where the abscissa a_Q of the auxiliary point Q on the x -axis is such that:

$$\frac{a_Q - z}{z} = \frac{H_B}{H_D} \quad [27]$$

The segment \overline{BD} is drawn, where B is on the diagonal line with $a_B = x_B$, and D is on the auxiliary line \overline{FQ} with $a_D = x_D$. The product compositions at time t are correct if the segment \overline{BD} is parallel to the x -axis.

The total amount of heat to be supplied to the reboiler is given by:

$$Q_r = \lambda H_D \int_z^{x_D^{\text{spec}}} \frac{dx_D}{y - x} = -\lambda H_B \int_z^{x_B^{\text{spec}}} \frac{dx_B}{y - x} \quad [28]$$

From a practical standpoint, the advantages of this operating mode are:

- the column always operates at its maximum fractionating capacity;
- column operation is very easy: only a level controller is necessary, which keeps the reflux drum hold-up at the specified value; no product switchovers are required;
- neither the yield nor the quality of the products is influenced by variations in the heating rate or interruption of the distillation.

Figure 8 Binary batch distillation at total reflux (three-ideal-stage column).

However, it should also be observed that unavoidable uncertainties in the feed amount, feed composition and column hold-up would act in such a way as to prevent reaching the desired purity specifications for both products. In order to ensure that the more valuable product is recovered on specification, the hold-up of the vessel containing this product should be set somewhat smaller than requested theoretically; a conventional temperature controller may be cascaded to the reflux drum level controller in order to adjust the level setpoint online, according to the desired purity requirements. Another way to reduce (and even eliminate) the effect of the uncertainties is using a middle-vessel batch column.

For multicomponent separations, a cycling operation may be employed: the column is operated at total reflux until a steady state is approached; distillate is then taken as total draw-off for a short period of time; then, the operation is switched back to total reflux, and the operating cycle is repeated.

Conclusion

As was noted in the Introduction, batch distillation as a way of separating a given mixture in multiple fractions is becoming more and more frequent, especially in the fine chemicals, pharmaceutical, biochemicals, food and beverages industries. While it is true that batch distillation usually consumes more energy than continuous distillation, it nevertheless provides more flexibility and requires less capital investment. This is an economic incentive, particularly when small volume or high added-value products are to be recovered. Still, there is a certain reluctance among operators to use this process. In fact, its unsteady nature, together with the need for monitoring, switching and discharging a series of cuts, may unavoidably confuse plant personnel.

From an engineering perspective, modelling and simulation of the operation is no longer as hard a task as it was in the past. The understanding of the process is fairly comprehensive (at least for conventional columns), so that all the operating steps characterizing a batch distillation process can be modelled in some detail. The availability of computer hardware at low cost makes it possible to solve all the model equations in a reasonably short time. It should be stressed that the availability of a reliable process model is a crucial issue for profitably utilizing an

existing batch column. If a good model is available, then it can be used to find out the optimal operating policy for the batch, i.e. to determine which are the sequence of reflux ratios during the batch and the strategy for reprocessing slop cuts between batches that would maximize a prescribed profit function. A process model can also prove useful for the closed-loop control of the operation. Advanced control strategies employ process models to get online estimations of the product compositions, thus eliminating the need to resort to expensive hardware analysers; more efficient control laws than the classical proportional plus integral algorithm can also be developed if a process model is available. Finally, process models can be employed within a training programme to instruct the plant personnel on how to interpret the column dynamics, and its response to process uploads: this may prove useful in improving the operator's confidence about this unsteady unit operation.

Introduction

Distillation dominates separation processes in the petrochemical industry and consumes nearly 95% of the total energy used in commercial separations. The energy used in distillation is approximately 3% of the total energy consumed in US industry. Distillation columns provide reliable, cost-effective separation for large throughputs and high purity product requirements. Distillation is an energy-intensive process and economics drive the need to optimize energy consumption in all aspects of its design.

In the pioneer years of distillation development, energy was comparatively cheap compared to capital costs. Reflux ratios of 1.2–1.5 times the minimum were commonly used to obtain an economical balance between operating and fixed costs. Columns were designed with large design margins to allow for feed changes and the lack of accuracy in physical properties, tray hydraulics and tray efficiency. By providing excess exchanger and tray capacity, product purity could be maintained by adjusting the tower operation to compensate for design uncertainty.

With the advent of the oil crises of the 1970s and 1980s, the energy costs became the major factor in column costs and created an urgency to find ways to reduce the energy requirements of distillation. Several techniques for analysing columns and plants were extensively developed and published in this era. Among the notable advances is 'exergy' analysis, developed primarily in Europe, and 'pinch' technology. This trend has subsided somewhat as more efficient methods of design and experience have eventually replaced the older technologies. The more exciting opportunities are in revamping older plants and designing new products. The introduction of high speed computers has also played a significant role in producing more accurate and more extensively evaluated designs. Physical and transport properties continue to be obtained more accurately. As the regulatory requirements for pollutant emissions and wastewater reduction became more stringent, many new studies has been directed towards reducing emissions from fired heaters and steam boilers used to supply heating requirements in columns. Wastewater

reductions of steam condensate blowdowns and cooling water make-up have become subject to tighter restrictions. Distillation column design will become more extensive and complex as the stringency of requirements continues to increase.

The primary objective of distillation column design is to produce the desired products with the minimum amount of energy expenditure and capital cost. The energy consumption in distillation columns is affected by the physical properties of the system, the utilities available for heating and cooling, the internals for contacting the liquid and vapour and the arrangement of the column separation sequence.

Measurement of Energy Performance

In order to determine the energy performance of a distillation column, two thermodynamic principles are applied to give a measurement method for determining the value of design improvements.

Availability or Exergy Analysis

The concept of availability or available useful work is a convenient way to determine the thermodynamic minimum amount of energy required for doing work in a steady flow process. The availability is referred to as exergy in Europe. The availability function is defined as:

$$A \equiv H - T_a S$$

where H is the enthalpy, S is the entropy and T_a is the reference temperature (298 K). A higher value of availability indicates that more work can be extracted as compared to a lower value. For example, high pressure steam is more valuable than steam at atmospheric pressure, although the latent heat values are about equal.

The change in availability represents the amount of shaft work that can be extracted from a system as it flows from an initial to final state. It also defines the minimum work required to achieve a change in a flowing system. This available shaft work, W_s , is defined in terms of the availability change, or:

$$-W_s \equiv \Delta A = \Delta H - T_a \Delta S$$

These properties are readily available from data references or process simulators and can be applied to all types of plant equipment in a process.

Heat Engines

A Carnot heat engine is useful in determining the theoretical maximum heat efficiency of an ideal, reversible distillation. The heat engine analogy consists of the simple column arrangement depicted in **Figure 1**. Heat is added at the bottom of the tower at a high level of temperature and then removed at the top of the tower at a lower temperature. This degradation in heat provides the work to separate the feed into the products. If we consider a distillation column as a heat engine, then the theoretical minimum work required for the heat engine is:

$$W_{\text{heat}} = Q_{\text{reboiler}}(1 - (T_a/T_{\text{reboiler}})) - Q_{\text{condenser}}(1 - (T_a/T_{\text{condenser}}))$$

The availability change of the streams in and out of the column is equal to this heat work minus a lost work term to account for thermodynamic inefficiency, or:

$$A_{\text{products}} - A_{\text{feeds}} = W_{\text{heat}} - W_{\text{lost}}$$

To account for real processes, a lost work term is included to account for irreversible changes within the column. This extra work is required to overcome pressure, temperature and composition driving forces. There are a number of commercial algorithms for determining each driving force contribution to lost

work. These lost work contributions are generally classified as:

1. Momentum loss due to pressure drop.
2. Heat transfer loss from temperature difference.
3. Mixing losses due to composition differences.

As the lost work term increases, the reboiler and condenser loads must increase in order to supply the same amount of useful work. As the driving forces approach zero, the lost work approaches zero and less energy is wasted.

For a particular column design, the availability of the feed and products and the theoretical minimum work are fixed. The lost work energy is solved by difference. The actual heat duty required for the distillation column will be the sum of the theoretical minimum plus the lost work, or $(W_{\text{heat}} + W_{\text{lost}})$. By comparing values of this sum, the designer has a yardstick in which to rate different column designs. For existing columns, a simple calculation of the total lost work will quickly focus as approach towards the most potentially beneficial areas. For example, if the lost work is less than 5% of the total heat duty, then this is probably within the design margin of the equipment and not worth pursuing.

Distillation Design Guidelines

A thermodynamic analysis provides information about the theoretical limits and does not address the issues of expense and implementation. Exergy studies should include capital costs with a payback period for a proper economic assessment.

The following list is a collection of design guidelines and practical constraints to be considered in searching for better energy schemes:

1. In order to distil vapour and liquids, the pressure must be below the critical pressure.
2. Accurate physical properties are required; proper models for nonideal solutions and azeotropes should be checked.
3. Thermally unstable components may limit the reboiler temperatures.
4. Air and/or water-cooling are preferred to the more expensive refrigeration.
5. Operational flexibility is usually required for feed changes and plant turndown.
6. Distillation columns do not work well at less than the minimum reflux ratio and at pinch points.
7. Heat integration may not be practical; transporting fluid over large distances may not be econ-

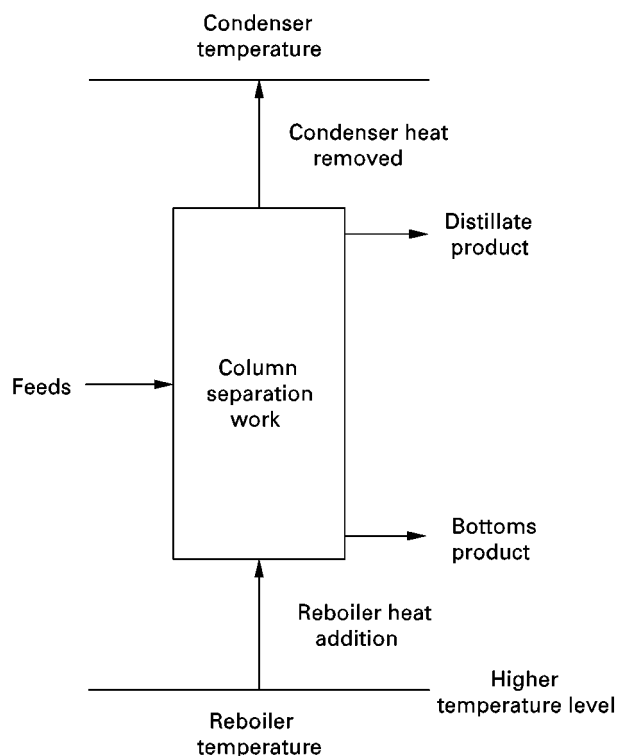

Figure 1 Distillation heat engine analogy.

omical; excessive temperatures result in film boiling; interaction between columns should be controlled.

8. Shipping weight and total height restrictions tend to limit the maximum number of trays or packing in one tower shell.
9. Lowering the operation pressure is a simple way to reduce energy consumption. Increasing pressure is the simpler way to increase capacity.
10. Lower energy consumption usually requires higher capital costs.

McCabe–Thiele Diagrams

One of the best visual aids for distillation is the ubiquitous McCabe–Thiele diagram. Despite its many limitations, the diagrams show the basic relationship between the equilibrium curve and the composition profiles throughout the column. A typical McCabe–Thiele diagram is illustrated in **Figure 2**. Heating or cooling changes the internal vapour and liquid flows and this effect can be seen as a shift in the slope of the operating lines in the diagram. For energy management, we are interested in seeking ways to minimize the difference (the composition driving forces) between the operating and equilibrium curves.

The absolute minimum energy expenditure will occur if external heating or cooling is applied to each stage to adjust the operating line so that it coincides with the equilibrium curve. This condition is impractical, since an infinite number of stages would be

required. The goal is to design a column with an approach as close as possible to equilibrium, but with an acceptable number of stages. A few successful designs exist that provide internal continuous cryogenic cooling in a small tray section. These types of columns that have continuous, internal heat exchangers are called dephlegmators.

There are numerous practical applications in the industry where adding *just a few select* external heating or cooling locations will provide a cost-effective reduction in energy.

Intermediate Heating and Cooling

Pumparounds

One of the earliest methods for saving significant amounts of energy was developed for crude units. Pumparounds are used extensively in atmospheric and vacuum towers to remove heat at selected stages. Liquid is withdrawn from an intermediate product stage, externally cooled and then pumped back to the column at a higher elevation. This arrangement is shown in **Figure 3**. The hot liquid from the tower is used to supply heat to several sources. The remaining cooled liquid is returned to the column and used to cool the column vapour. Pumparounds have the effect of shifting the operating lines *at select intervals* closer to the equilibrium curve to improve energy consumption. The sub-cooled liquid provided in the pumparound reduces the cold utility requirements and size of the overhead system. The cooling tower and condensers are less expensive and thermal and wastewater pollution is reduced. The hot pumparound liquid has the additional role of recovering heat supplied in the feed furnaces by transferring it to feed pre-heat, steam generation and heating for downstream units.

Intercondensers and Interreboilers

Another useful technique for reducing the utility loads is to add intermediate exchangers. **Figure 4** shows the effect of adding an inter-reboiler on a McCabe–Thiele diagram. The benefit of this modification is that the *reboiler* heat duty is reduced by the amount of duty used in the inter-reboiler. Since the temperature level will be less than the reboiler temperature, it may be possible to use a process stream for the heating. If this heat integration is feasible, then significant savings of the reboiler utility, such as high pressure steam, can be achieved. The internal column flows below the interreboiler stage will be reduced, but the stage requirement will increase since the operating line will be closer to the equilibrium curve. For this reason, the addition of intermediate exchangers is

Figure 2 Typical McCabe–Thiele diagram.

Figure 3 Pumparound section.

usually economical only when a few extra stages will be required. An analogous result will be obtained with an inter-condenser. The condenser utility load will be reduced, the internal flows in the stages above the condenser will be reduced, but more stages will be required. The benefits of intermediate cooling or condensing are particularly economical when an expensive refrigerant is used as the condenser cooling medium.

There are semi-rigorous calculation methods for determining how much heat can be added or removed

Figure 4 McCabe-Thiele diagram with interreboiler.

Figure 5 Column grand composite curve.

at a particular temperature level. One technique, which is an extension of 'pinch' technology, is to generate a column grand composite curve (CGCC). These curves plot the heat transferred between the vapour and liquid versus stage temperature. A typical example is shown in Figure 5. The best opportunities for using intermediate heat exchangers exist in the regions where large amounts of heat are exchanged at temperatures significantly different to that of the reboiler or condenser. When deciding upon how much heat will be added or removed, one should consider the extra stages that will be required and allow for a suitable design margin for flexibility. If this type of region exists near the feed locations, then feed conditioning may be an option. Adding a feed exchanger will generally be less expensive than adding an intermediate exchanger on the column.

Feed Conditioning

The feed is introduced into the column where the temperature and composition roughly match the column profile. The feed is at higher pressure in order to flow into the column. The location of the feed stream can be optimized with a few judicious choices with a process simulator. The feed quality and location can also be adjusted within limits to lower the reboiler or the condenser duty, but not both. The best opportunities for utilizing feed exchangers are during revamps when there is excess vapour- and liquid-handling capacity in one section of a column. For example, if the trays above the feed can handle more fluid traffic without modification, but the bottom section trays are capacity-limited, then installing a feed pre-heater can be used to unload the bottom traffic. The

energy penalty will be increased condenser duty, but internal modifications or tower replacement may be avoided.

Prefractionation

In a multi-component column separation, the presence of lighter nonkey components will limit the purity of the light key. At the top of the tower, the light key will actually be the heavier component and its composition will reach a maximum value and then decrease as it is fractionated from the lightest components. By removing these lighter non-key components from the feed in a pre-absorber, the column can now produce a higher purity product. Removing the light components from the feed reduces the flow to the column, so that pre-absorbers can be used to unload the rectifying section of an existing column. In analogous fashion, the addition of a pre-stripper will unload heavy components from the stripping section of a column. **Figure 6** shows an illustration of a pre-stripper column arrangement. The additional feed to the last column will usually provide a modest energy saving for that column.

Heat Pumping

A significant saving in condenser duty can be achieved by compressing the overhead vapour to a temperature that can be used to reboil the bottoms liquid. A typical heat-pumped column is shown in **Figure 7**. The compressor is a significant addition to the total capital costs. This scheme is feasible if the distillation involves a close boiling mixture where the top and bottom temperatures are not significantly different. The most common industrial application is propane/propylene splitters, which require large

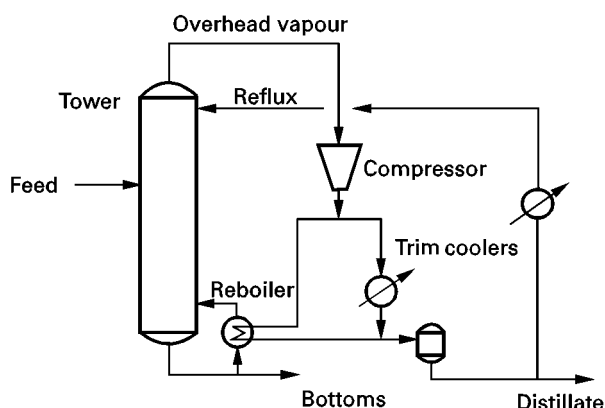

Figure 7 Heat-pumped column.

amounts of heating and cooling energy. A large reduction in cooling water and wastewater products provides a large incentive to heat pump these types of columns.

Extractive and Azeotropic Distillation

Instead of modifying the heat exchange in columns, a reduction in energy is possible by altering the physical properties of the mixtures. For mixtures that are difficult to distil, a solvent may be added to increase the relative volatility of the mixture. If a suitable solvent can be found with a relatively low volatility, then the separation process is known as extractive distillation. A typical extraction distillation column arrangement is illustrated in **Figure 8**. This process is economical to use when a small amount of inert solvent can permit an easier (less expensive) separation of the original products. An additional tower is required to remove the solvent from the heavier product.

Figure 6 Prestripper column sequence.

Figure 8 Extractive distillation configuration.

If the addition of a light component can alter an azeotrope, then the process is termed azeotropic distillation. The entrainer often forms a new low boiling azeotrope that is relatively easy to separate from the heavier product. The entrainer is separated from the lighter product with an additional column and/or condensed to two liquid phases that are separated in a settling drum. Azeotropes are common in the specialty chemicals industry and most configurations are proprietary.

Extractive or azeotropic distillation should be considered a last resort option. Finding a suitable solvent or entrainer that is inexpensive and relatively inert is the key to a practical design.

Column Internals Selection

The choice of internals can have impact on energy efficiency, control response and downstream equipment. The function of trays or packing is to promote efficient heat and mass transfer by intimate contacting of the vapour and liquid. For trays, a portion of the vapour energy is expended in the form of pressure drop to produce liquid droplets and to overcome the liquid head on the tray. In contrast, the contact area in packing is mainly created by the spreading of liquid over the metal surfaces and by rivulet flow. For these reasons, the pressure drop in packing is significantly less than in trays.

This becomes an important characteristic in high vacuum distillation, where the pressure and temperature changes dramatically from top to bottom as pressure drop increases. A tower pressure change from 50 mm Hg to 25 mm Hg will double the volumetric flow of vapour and will have a major impact on the tower size. The normal design pressure drop for *one* tray is 3–5 mm Hg, which will limit the number of trays that can be used. Low pressures and temperatures in the top of the tower have an impact on the cost and performance of the condenser and vacuum system. Using lower pressure drop internals reduces the exergy losses associated with momentum and temperature difference. For these reasons, packed ns are favoured for vacuum distillations.

There also is an advantage to lowering pressure drop in a column when the overhead vapour is fed to a compressor. Changing from trays to packing during a capacity increase revamp is a convenient way to avoid compressor changes. If the pressure drop through the tower is reduced, the increase in compressor suction pressure may just compensate for the new capacity increase.

By virtue of lower pressure drop and liquid hold-up, packed columns have relatively faster response to changes in flow and composition changes. The faster

acting control of the column reduces the energy waste of recycling off-spec product.

Column Sequencing

The sequencing and arrangement of columns to obtain multiple products has a major impact on energy and capital costs. In order to separate X amount of products, a minimum of $X - 1$ simple, conventional columns are required. If the products are removed as distillates, the arrangement is called a direct sequence. The direct sequence is favoured when the distillations are at high pressure and require refrigeration, such as olefin production. An indirect sequence is used if the products are withdrawn as bottoms. Indirect sequencing favours lower heat consumption. In many petrochemical plant configurations, both sequences are used or mixed as dictated by the many product requirements. An illustration of the direct and indirect sequence arrangement is given in Figures 9 and 10.

A number of heuristics have evolved from experience of sequencing columns. A few of the more common guidelines are listed below:

1. Leave the most difficult separations to the end. The binary separation of high purity products requires larger towers and higher energy consumption when non-key components are present.
2. Direct sequences are favoured when heating costs are less than cooling costs.
3. Less energy is expended when the top and bottom product flows are about equal.

The column sequencing depends upon numerous factors that make each case different. Refining, ethylene, aromatic and specialty chemical plants all have unique properties and idiosyncrasies that make generalizations difficult. The column arrangements

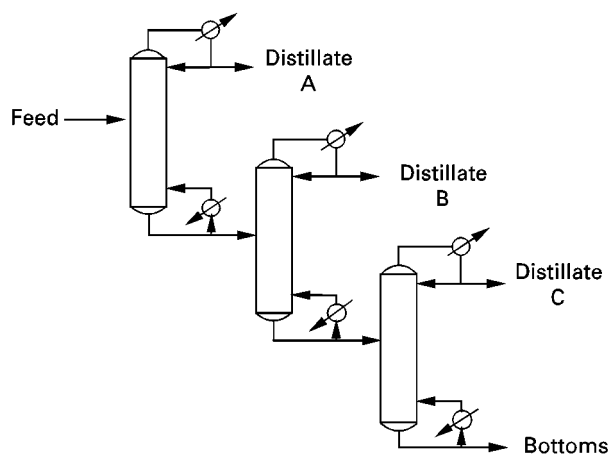

Figure 9 Direct column sequence.

Figure 10 Indirect column sequence.

are commonly integrated with the total plant optimization to minimize overall capital costs, energy consumption and pollution reduction. Techniques such as pinch technology and exergy analysis are used to evaluate the global effect of equipment changes to arrive at the best plant design, which may not coincide with the best column design.

Distributed Distillation

Distributed distillation is a separation technique that minimizes the lost work due to mixing and recycling of fluids within a column. The energy consumption can be reduced by making a separation between the most volatile and least volatile components with the rest of the components distributed between the top and bottom. An easy separation between components

with the highest relative volatility will yield the minimum boil-up and reflux for any column. This concept is illustrated in Figure 11. A distributed column sequence will theoretically consume less energy, but will require more columns. The energy savings have been reported to be upwards of 30%.

To lower the capital costs, the column can be thermally coupled as described in the Petlyuk configuration shown in Figure 12. Thermal coupling is used to describe the situation when liquid from a column is used to supply reflux and vapour is used to supply boil-up to another column. Several variations of this arrangement are used to eliminate heat exchangers in column designs. Combining the two columns together and providing a partition to form a *divided wall column* reduces the capital cost. Three products can be produced from one column, one reboiler and one condenser, as compared to a conventional sequence that requires two columns and four exchangers. The commercial use of divided wall columns tends to be limited to separations with significant amounts of intermediate components.

The Future of Energy and Distillation

Distillation is a mature separation technology and will remain dominant in the near future. Despite the high energy requirements, distillation is a cost-effective method for separating large quantities of material into high purity products. Other separation methods are specific in application and lack the

Figure 11 Distributed column sequence.

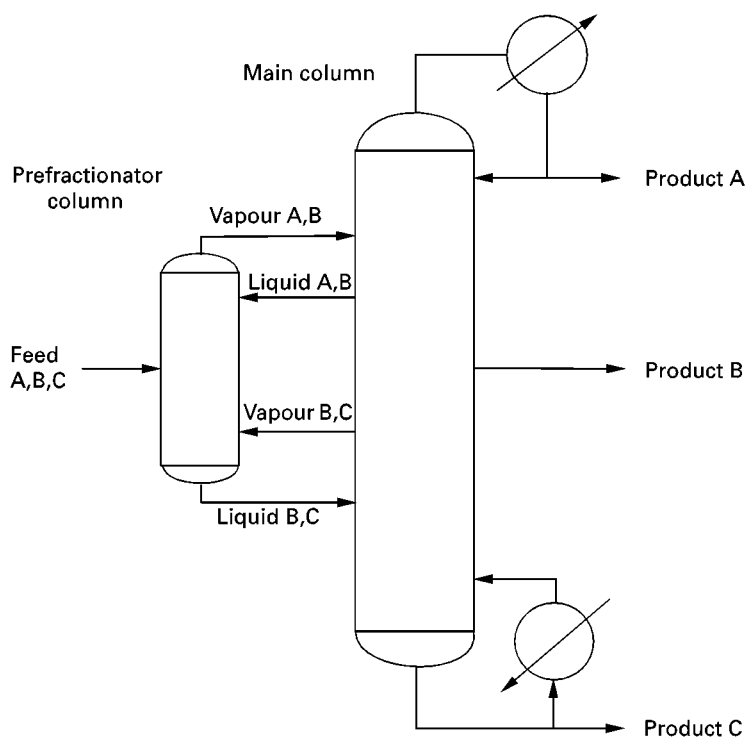

Figure 12 Petlyuk configuration.

versatility of distillation. Current research efforts have been evolutionary and the majority of the industry is reluctant to test any technology that has not been commercially proven. Therefore, even promising new technology changes are slow and cautious. Many research efforts have started to combine the best features of different separation methods to save energy and capital costs. The future of distillation will always depend upon energy costs and change will occur when these costs become unacceptable.

Introduction

In the first half of the twentieth century, extractive distillation (ED) became an important industrial process when World War II demanded high purity toluene for explosive production and butadiene for synthetic rubber production. Over the years, substantial developments in ED have been carried out in terms of novel solvent discovery for a particular separation, as well as the development of more sophisticated ED tower internal designs. In the petroleum and petrochemical industries, ED has been found effective in separating mixtures of aromatics/nonaromatics, diolefins/olefins, olefins/paraffins and naphthenes/paraffins.

This article will briefly review the basic concept of ED, and summarize the development of ED technologies for the applications in the following areas:

1. Aromatic purification from refining and petrochemical streams.
2. Cycloparaffin (cyclohexane or cyclopentane) recovery from naphtha or natural gas liquid.
3. Light olefins from light hydrocarbon mixtures.

The basis of ED is the increase of relative volatility between the close-boiling components caused by introducing a selective solvent, which has stronger affinity with one type of the components in the mixture. If there is a single liquid phase (no phase separation), the solvent selectivity can be measured from the experimentally observed relative volatility (α) between the key components in the presence of solvent as:

$$\alpha = (Y_1/X_1)/(Y_2/X_2)$$

where X_1 and X_2 are the mole fractions of components 1 and 2, respectively, in the liquid phase, and Y_1 and Y_2 are those in the vapour. All compositions are measured on a solvent-free basis.

In some cases, liquid-phase separation may occur in the ED tower, especially in the upper portion of the tower where less polar components are concentrated. Under this condition, the solvent phase can reject a second liquid phase, which can be defined as the raffinate liquid phase. The liquid in the solvent-rich phase is defined as the extract liquid phase. The solvent selectivity is determined by the relative vola-

tilities of the key components in the two interrelated liquid phases and the common vapour phase, according to the following formulae:

$$\alpha_r = (\gamma_{1r}p_{1r})/(\gamma_{2r}p_{2r})$$

$$\alpha_e = (\gamma_{1e}p_{1e})/(\gamma_{2e}p_{2e})$$

where α_r and α_e are the relative volatilities of components 1 and 2, respectively, in the raffinate phase and extract phase; γ_{1r} and γ_{2r} are the activity coefficients in the raffinate phase, and γ_{1e} and γ_{2e} are the activity coefficients in the extract phase; and p_{1r} , p_{2r} , p_{1e} , and p_{2e} are the vapour pressures of the pure components (which can be estimated from an Antoine equation).

A schematic diagram of a typical ED process is presented in **Figure 1**. During a normal run, a polar, high-boiling (low volatility) solvent is introduced to near the top of the ED tower. As the nonvolatile solvent flows down the column, it preferentially associates the more polar components in the ascending vapour mixture, thus increasing the relative volatility between the polar and less polar components. The process feed stream is introduced to the middle portion of the ED tower. The more polar components are concentrated in the rich solvent, exiting the bottom of the ED tower, while the less polar components are concentrated in the overhead raffinate stream. The tower reflux stream is provided to knock down the entrained solvent from the overhead raffinate stream.

The solution, rich in polar compounds from the bottom of the ED tower, is fed to the solvent stripper, where the polar components are stripped from the solvent by heat alone or by heat and a stripping gas, such as steam. The lean solvent is then recycled to the ED tower from the bottom of the stripper.

Aromatic Purification from Refining and Petrochemical Streams

Advantages and Principle of ED Technology

Although liquid-liquid extraction (LLE) technologies have dominated the industrial processes for purifying benzene, toluene, xylene (BTX) aromatics from refining and petrochemical streams, ED technologies have gained ground quickly since the 1980s for more recent grassroots plant installations. In comparison to LLE, ED has the following advantages:

1. *Lower capital costs.* ED requires two major process units (ED tower and solvent stripper), while

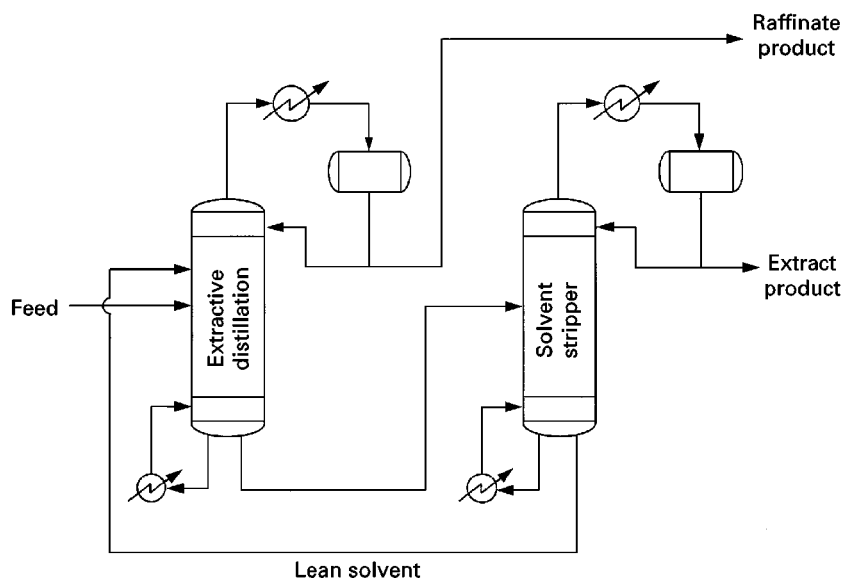

Figure 1 Configuration of an ED process.

the popular LLE, using sulfolane as the solvent, requires four major process units, including LLE tower, extractive stripper, solvent recovery column, and raffinate wash tower (see Figure 2).

2. *Higher operational flexibility.* LLE uses only solvent selectivity (polarity) for separation, while ED uses both solvent selectivity and boiling point for separation, so it has one extra dimension for operational flexibility.

3. *Less physical property restrictions.* Interfacial tension and density difference between the liquid phases are important concerns for LLE, but not for ED.

The principle of ED for aromatic purification was studied as early as 1944. One example was the recovery of toluene from paraffins using phenol as the selective solvent. The effect of phenol on a paraffin-toluene mixture is plotted in liquid-vapour

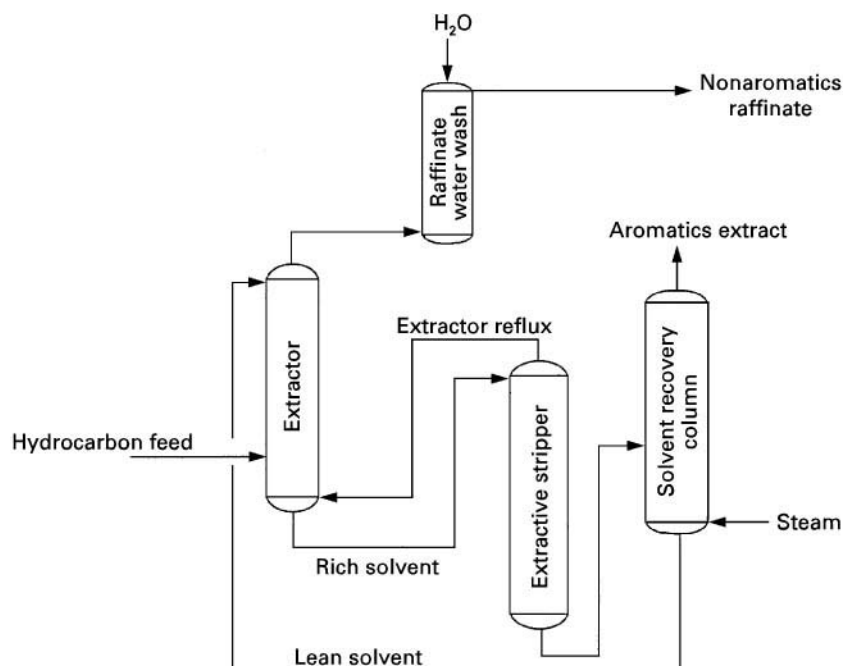

Figure 2 Configuration of liquid-liquid extraction using sulfolane for aromatic recovery.

Figure 3 Effect of phenol on the vapour-liquid equilibrium of paraffin and toluene. Numbers on curves refer to mol% solvent in liquid.

diagrams as shown in Figure 3, in which the paraffin is considered as a hypothetical octane having the same boiling point as toluene. In the absence of phenol, there exists an azeotrope of paraffin and toluene. However, at 50 mol% phenol, the azeotrope is destroyed and the mixture is easily separated; at 100 mol% phenol, the separation between paraffin and toluene becomes very easy. Figure 4 illustrates the effect of phenol on the change in relative volatility between paraffin and toluene. Phenol causes an increase of activity coefficient for both paraffin and toluene, but the activity coefficient of the paraffin increases to a greater extent than that of toluene. Therefore, the relative volatility of paraffin over toluene can be increased from 1.0 (no separation) to 3.7 (easy separation) at near zero hydrocarbon concentration in phenol (infinite dilution).

Figure 4 Effect of phenol on the activity coefficient of paraffin and toluene.

The vapour-liquid equilibria of the paraffin-toluene-phenol system were applied to test a commercial ED tower for toluene purification. As shown in Figure 5, the McCabe-Thiele diagram, drawn on a phenol-free basis, was used to carry out the theoretical calculations from tray to tray in the ED tower.

The calculated results were then compared with the actual results generated from a commercial ED tower with 2.1 m diameter and 65 trays. The hydrocarbon feed tray and the solvent feed tray are located at trays 19 and 39 (counted from the bottom of the tower), respectively. The tower was operated at a solvent-to-feed ratio (S/F) of 2.5, a reflux-to-overhead ratio (R/D) of 2.75, and reboiler temperature at 170°C under 1.3 atm bottom pressure. On the basis of the charge, overhead and bottoms analyses, tray-to-tray calculations were made.

Figure 6 shows the calculated concentration profiles for each component plotted against theoretical tray number. It also shows the plot of the tray analyses against actual tray number. The overall efficiencies calculated over small sections of the tower are given in Table 1. The average of the overall tray efficiencies throughout the tower is about 50%.

Based on the above principle, much more rigorous algorithms for tray-to-tray calculation of ED towers for multicomponent systems have been developed in

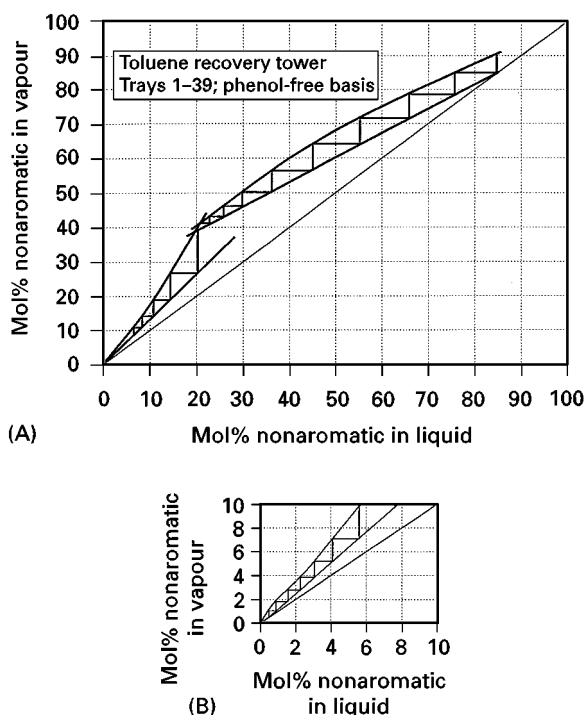

Figure 5 McCabe-Thiele diagram for paraffin and toluene separation in the presence of phenol. Part (B) is an enlargement of part of the diagram in (A).

recent years, with the help of advanced vapour-liquid equilibrium theories and high-speed computers.

Handling Two Liquid Phases in ED Towers

One of the challenges of ED technology for aromatics purification is the handling of the possible formation of two liquid phases in the upper portion of the ED tower where nonaromatics are concentrated. The occurrence of a second liquid phase is due to the fact that the nonaromatics, such as paraffins, naphthenes and olefins, have significantly lower solubility in the polar solvent than aromatics.

One way to solve the problem of two liquid phases in the ED tower is to select a polar solvent that has

enough solvency to dissolve both aromatics and nonaromatics in the mixture under process condition. In general, however, solvents with a high selectivity for compounds to be separated will have a reduced solvency (capacity), and vice versa. The selectivity versus solvency of the common commercial solvents for aromatic extraction is shown in Figure 7. Therefore, in order to eliminate two liquid phases, one may have to compromise the solvent selectivity, sometimes to a great extent.

A better way is to cope with two liquid phases in the ED tower, without sacrificing the solvent selectivity, for the following reasons:

1. Two liquid phases normally reduce the solvent selectivity in the three-phase equilibrium (vapour-liquid-liquid) condition in the ED tower. However, this can be compensated by intrinsic selectivity of a highly selective solvent. For example, the performance of sulfolane was

Table 1 Tray efficiency of ED tower for toluene purification

Section of tower trays	Theoretical trays	Actual trays	Overall efficiency (%)
<i>Below phenol feed tray</i>			
1-3	1.8	3	60.0
4-7	2.7	4	67.5
8-11	2.1	4	52.5
12-15	1.5	4	37.5
15-18	1.8	3	60.0
23-27	2.1	4	52.5
27-30	2.5	4	62.5
31-34	2.65	4	66.0
35-39	2.35	5	47.0
<i>Above phenol feed tray</i>			
43-65	10.8	23	47.0
49-65	8.6	17	50.7
57-65	4.5	9	50.0
61-65	2.8	5	56.0

All trays numbered from bottom of tower.

Figure 7 Selectivity versus solvency (solubility) of the common commercial solvents. DEG, diethylene glycol; TEG, triethylene glycol; DMS, dimethyl sulfoxide; NMP, *N*-methyl pyrrolidone.

compared with those of *N*-formyl morpholine (NFM) and *N*-methyl pyrrolidone (NMP). The ability of these solvents to enhance the relative volatility of *n*-heptane over benzene (an aromatic and nonaromatic separation) in a one-stage equilibrium cell was determined. Table 2 shows that, although two liquid phases were observed using sulfolane as the solvent, sulfolane still gave a better performance than the other solvents where a single liquid phase existed in the mixture.

- Two liquid phases have no ill effects on the efficiency of small tray or packed towers with diameter from 0.08 m to 0.46 m. However, in larger towers, the heavy liquid phase tends to accumulate on the tray if the liquid phases are not well mixed. This problem can be eliminated by tray designs promoting gas agitation, forcing the two liquid phases to behave as a homogeneous liquid. For larger packed columns, liquid-liquid redistributors are specially designed to allow separate distribution of the two liquid phases.

Computer simulations have been developed which are capable of accurately predicting the development of two liquid phases in the ED tower. In one approach, the simulation algorithm starts from linearized pressure, temperature and concentration profiles and feed conditions given by the program operator. New estimates of composition are solved, using the material balance and equilibrium relationship for each tray. Then the equilibrium constants are re-estimated and a new temperature gradient is established to calculate a tray-by-tray energy balance. Accumulated errors are calculated for the energy, material and equilibrium balances. Appropriate column operation restraints are factored in at this point. A correction factor is found for the temperature, rate profiles, and liquid composition profile by inverting the accumulated error matrix. These correction factors are used to form new iterative estimates of composition to start the process again until the correction factors are small enough to call the components converged.

Table 2 ED solvent screening for aromatics recovery

Solvent	Relative volatility (<i>n</i> -heptane/benzene)	Number of liquid phases
Sulfolane	3.9	2
DMSO	3.6	1
NFM	3.1	1
NMP	2.6	1

Feed: 20% *n*-heptane and 80% benzene; pressure 1 atm; DMSO, dimethyl sulfoxide; NFM, *N*-formyl morpholine; NMP, *N*-methyl pyrrolidone.

Multicomponent vapour-liquid and liquid-liquid equilibria solutions are required for the algorithm. Two activity coefficient models, NRTL (nonrandom two liquids) and UNIQUAC (universal quasichemical), are readily extendable to multicomponent systems and capable of such solutions. Experimental activity coefficients, γ , at infinite dilution are used for calculating binary parameters for the NRTL equation. These parameters are then tested using experimental liquid-liquid ternary data, experimental vapour-liquid equilibrium data, and data from pilot plant or commercial plant. The NRTL equation is used in the algorithm to calculate activity coefficients and is given in the following equations:

$$\ln \gamma_1 = x_2^2 [\tau_{21}(G_{21}/(x_1 + x_2 G_{21}))^2 + \tau_{12}(G_{12}/(x_2 + x_1 G_{12}))^2]$$

$$\ln \gamma_2 = x_1^2 [\tau_{12}(G_{12}/(x_2 + x_1 G_{12}))^2 + \tau_{21}(G_{21}/(x_1 + x_2 G_{21}))^2]$$

where

$$\ln G_{12} = -\beta_{12}\tau_{12}$$

$$\ln G_{21} = -\beta_{21}\tau_{21}$$

$$\tau_{12} = (\eta_{12} + S_{12}T)/RT$$

$$\tau_{21} = (\eta_{21} + S_{21}T)/RT$$

and where G_{ij} , η_{ij} , S_{ij} and β_{ij} are empirical constants, γ_i is activity coefficient, R is the gas universal constant, T is absolute temperature, and x_i is liquid phase mole fraction of component i .

The simulation uses a Newton-Raphson-based flash algorithm that checks for two liquid phases by checking Gibbs free energies for components the program operator lists as possible second liquid phase formers. If two liquid phases are indeed present, regular solution theory provides a method of combining the liquid-phase activity coefficients.

State-of-the-art ED Technologies

The modern state-of-the-art ED technologies for BTX aromatic purification are based on several solvent systems: sulfolane, NFM and NMP. Proprietary cosolvents may be blended into the base solvent to enhance the performance in specific applications.

Table 3 summarizes the key performance parameters of LLE and ED for aromatics recovery. ED process can provide up to 25% savings in capital investment as compared with the commercially available LLE processes. This saving is attributable to the

smaller number of operating units, as mentioned above. The ED process recovers more xylenes but less benzene than LLE processes.

The Morphylane[®] process offered by Krupp Koppers uses NFM as the selective solvent. A schematic diagram of the Morphylane[®] process is given in Figure 8. The diagram is very similar to the general ED process scheme as shown in Figure 1, except the nonaromatic vapour exiting the top of the ED tower contains a small amount of NFM solvent (0.9 wt%), which must be recovered. Two methods are used for this solvent recovery, both of which require additional equipment and expense: (1) a separate solvent recovery column; and (2) additional trays or packings fitted to the top of the ED tower (above the solvent tray), using nonaromatics as the reflux to flush NFM back into the ED tower. To use the second method,

the feedstocks to the ED tower must contain only very small amounts of critical components, such as methylcyclohexane and dimethylcyclopentane in pyrolysis gasoline feedstock, or C₇ olefins in reformate feedstock.

The Morphylane[®] process is available in commercial applications for recovering high purity benzene from C₆ fraction, or pure benzene and toluene from the C₆–C₇ fraction of reformate or pyrolysis gasoline. For example, the process has been commercially tested with a feedstock from a mixture of C₆ reformate fraction and a C₆ fraction of a pyrolysis gasoline. The plant had a top-fitted solvent recovery system. The results are summarized in Table 4. Approximately 98% benzene recovery with 99.9% benzene purity was achieved with this process. This process, however, has not been applied to the recovery of higher

boiling aromatics, such as mixed xylenes or C₉⁺ and higher aromatics, probably because of the relatively low boiling point of NFM.

The GT-BTXSM process offered by GTC Technology Corporation is available for recovering not only benzene and benzene/toluene, but also a full range of aromatics (benzene, toluene and xylenes) with high purity and recovery. The process uses a proprietary sulfolane-based solvent blend. Due to the high boiling point of the solvent, the process is very effective in recovering higher boiling aromatics, such as xylenes

and C₉⁺ and higher aromatics. Unlike the Morphylane[®] process, the overhead nonaromatics stream from the ED tower in the GT-BTXSM process contains essentially no solvent, and does not require a separate solvent recovery tower.

A hybrid concept of the GT-BTXSM process can be used to increase substantially the capacity of the liquid-liquid extraction unit and improve the quality of the benzene product, through retrofitting of the existing unit. The retrofitting can be carried out using this hybrid concept without requiring extensive modifications, investment or lengthly shutdown time. Figure 9 shows a new process using a hybrid of the sulfolane liquid-liquid extraction process with the GT-BTXSM process that bypasses part of the feed around the original extraction section. In the hybrid scheme, the ED tower is better suited to purifying the benzene-rich feed than the liquid-liquid extraction unit, and it is not subject to the maximum aromatics limit in the hydrocarbon charge. The ED tower nonaromatic stream (rich in cyclohexane) may be recycled to the reformer unit for producing more benzene, while the raffinate stream from the liquid-liquid extractor (rich in paraffins) could be routed to gasoline blending or used as a feedstock for naphtha cracking to produce ethylene and pyrolysis gasoline. The major changes are modifications of the solvent system to be compatible with both extraction operations and to make the appropriate tie-ins to the ED tower.

**Figure 9** Hybrid scheme for aromatic recovery process expansion.

Cyclohexane Recovery from Naphtha or Natural Gas Liquid

In recent years, ED technology has also been applied to the separation of paraffins and cycloparaffins, a much more difficult separation than aromatics and nonaromatics. One of the major developments was cyclohexane recovery from naphtha or natural gas liquid (NGL) streams. Cyclohexane, an important raw material for the nylon industry, exists naturally in naphtha and NGL streams. However, recovery of high purity cyclohexane from naphtha or NGL through conventional distillation is virtually impossible, owing to the close-boiling C_7 isomers in the streams. Since the polarity difference between cyclohexane and C_7 isomers is substantially smaller than that for aromatic and nonaromatic compounds, no extractive solvent has been found that can effect the separation. However, through the use of a cosolvent (to enhance the solvency of the mixed solvent), an ED process has been commercialized to recover high purity cyclohexane directly from an NGL fraction containing 85% cyclohexane.

Many solvent blends show synergistic improvement over what would be expected by pure component mixing. To test the concept, experiments were conducted in a one-stage vapour-liquid equilibrium (VLE) cell to compare the selectivity of five solvents. To a hydrocarbon mixture of 85 wt% cyclohexane (C_6) and 15 wt% 2,3 dimethylpentane (2,3-DMP), a selective solvent or a mixed solvent was added, at a solvent-to-feed ratio (S/F) of 7.0. The relative volatility of 2,3-DMP over C_6 was measured in the equilibrium cell with various solvents. Table 5 presents a comparison of relative volatilities obtained for five solvents tested, including a proprietary mixed solvent (MIST) from Phillips Petroleum Company. MIST solvent, discovered by investigating the combinations of many other solvents, has a significantly higher relative volatility than the other single solvents.

Computer simulations were carried out to confirm the results on solvent screening from the one-stage

^bSimulation failed to converge.

Premises: 99% C_6 recovery, overhead product allowed to vary; S/F weight ratio = 16; 25 equilibrium stages (solvent fed on stage 24, hydrocarbon fed on stage 12); reflux fixed at 0.48 (hydrocarbon feed).

VLE cell for the mixed and single solvents shown in Table 5. These simulations were based on experimental physical property data, such as the infinite dilution activity coefficients of binary solvent-hydrocarbon mixtures. Again, NRTL thermodynamic correlations were used to predict the occurrence of two liquid phases and a Newton-Raphson convergence method was used to carry out the simulations.

Simulations of a ED process separating an 85/15 wt% C_6 /2,4-DMP mixture were made to compare the MIST solvent with four common extraction solvents, ethylene (EG), triethylene glycol (TEG), sulfolane and N-methyl pyrrolidone (NMP). The simulations were for a 25 theoretical stage ED tower at a S/F ratio of 16. The C_6 recovery in the extract stream was specified at 99.0% and the overhead raffinate product was allowed to vary. Table 6 shows that the MIST solvent has a separation factor 5 times greater than TEG, which has the highest separation factor of the single solvents.

The MIST solvent was first tested in a 150 mm diameter ED pilot plant using as the feedstock a refinery stream that had an average composition as shown in Table 7. Based on the successful pilot plant study, a commercial plant purifying 100 metric tonnes per day cyclohexane was designed, constructed and commissioned in 1991.

butenes, the feedstock to butadiene units, were also in great demand. ED process technology was developed to recover high purity *n*-butenes suitable for producing butadiene to feed the synthetic rubber process. In this case, the selective solvent, developed by Shell Development Company in Houston, Texas, USA, was a mixture of 85% acetone and 15% water.

Later, furfural was used as an ED solvent for separating isobutane from butene-1, *n*-butane from butene-2, and butene-1 from butadiene. As shown in Figure 10, furfural was tested in an ED tower consisting of two 50-tray sections in series for separating butene-2 from *n*-butane. Solvent was charged to a tray, which was several trays from the top of the first section (A), and flowed to the bottom of this section. It was pumped together with dissolved hydrocarbons to the top of the second section (B), and

withdrawn from the bottom of this section together with hydrocarbon bottoms. The solvent and bottoms are separated in a smaller 20-tray stripper tower, the solvent-free bottoms being removed as overhead and stripped solvent circulated back to the ED tower. Hydrocarbon feed is charged at some point below the solvent feed, near the bottom of the first section or top of the second section of the ED tower.

For *n*-butane and 2-butene separation, the purity of 2-butene was 94.6 vol% with only 39.4 vol% recovery. For mixed butanes and mixed butenes separation, the purity of mixed butenes was 88.7 vol% with 96.7 vol% recovery, and for butadiene and butenes separation, the purity of butadiene was 96.9 vol% with 89.7 vol% recovery. Obviously, these results did not meet the industrial requirements for producing high purity product with high recovery.

Further studies were carried out to screen solvents for olefin and paraffin separations. For example, a comprehensive solvent screening study was conducted for *n*-butane and butene-2 separations. Eighty solvents were evaluated, including ester-type solvents containing hydroxyl groups, aldehyde groups, amine groups, nitrile groups, nitro groups, ketone groups, nitrogen; ether-type solvents; and miscellaneous solvents. It was found that aniline and furfural were the most selective solvents. The VLE data for *n*-butane and 2-butenes in furfural and aniline solvents are given in Figures 11 and 12. Although *N*-formyl morpholine was also tested among the nitrogen-containing solvents for *n*-butane and 2-butenes separation,

**Figure 10** Schematic ED process diagram for separating 2-butene and *n*-butane.

Figure 11 Vapour-liquid equilibrium of *n*-butane and 2-butene in Furfural. Solvent dosage: ●, 3.7; ○, 4.5. Pressure, 3862 mmHg.

for unknown reasons the solvent was not considered for commercialization until recently.

Krupp Koppers has offered the BUTUNEX process, an ED process using *N*-formyl morpholine as the selective solvent, for recovering 1-butene and 2-butene from C_4 hydrocarbon streams. On the basis of such a feedstock with the composition of 25.6% isobutane, 32.7% *n*-butane, 26.6% 1-butene and 15.1% 2-butene, the following yields can be

achieved:

1-Butene	95.6%
2-Butene	99.1%
Butanes	98.9%

The purity of 1-butene and 2-butene products can be 99.6% and 95.9%, respectively.

Conclusions

Since the 1940s, ED technology has gone through extensive development for solving many difficult separation problems in the petroleum and petrochemical industries. The development in cosolvent selection tailored for a specific separation and the advancement in tower internal design have made ED a competitive process. In many cases, ED processes can be more efficient and economical than conventional LLE in terms of capital investment, energy consumption and ease of operation. It is anticipated that the ED technology will be selected more frequently in the future for the petroleum and petrochemical industries.

Freeze-Drying

G.-W. Oetjen, Chemical Engineering,
Lübeck, Germany

Copyright © 2000 Academic Press

Introduction

Freeze-drying is a process, in which a product is first frozen and then dried by sublimation of the ice. The total process involves four steps: freezing; sublimation of the ice, called main drying (MD); desorption of the water bound to the solid, called secondary drying (SD); and packing in containers to exclude absorption of water and/or oxygen from the atmosphere. By freeze-drying a product unstable in water is transformed into a dry, stable product. The process has to be developed to satisfy four demands on the finished product: its volume remains that of the frozen substance; the structure and the biological activity of the dried solid correspond as far as possible to those of the original substance; the dried product remains stable during storage, if possible at temperatures up to $+40^{\circ}\text{C}$ and for up to 2 years; and with the addition of water the original product is quickly reconstituted. This article summarizes the problems and solutions to achieve these aims.

Theoretically, sublimation of ice can be done at atmospheric pressure; however, the vapour pressure of ice between -10°C and -40°C is approximately 2.6–0.13 mbar and 1 kg of ice has a volume of approximately 470 m^3 at -10°C and 8400 m^3 at -40°C . To transport these volumes at atmospheric pressure the gas volume has to be approximately 400–8000 times larger than that of the vapour. Therefore all freeze-drying plants today are vacuum plants, in which the air is reduced to some 10% of the vapour pressure, to allow the free flow of vapour at velocities up to 100 m s^{-1} .

The first organ tissues were freeze-dried in 1890 and in 1932 a vacuum freeze-drying plant was built, but only after 1940 did it become an industrial process with the freeze-drying of blood plasma and penicillin.

Freezing

Structure of Water and Ice

In a water molecule the two H atoms form an almost tetrahedral angle with a strong dipole moment. A shell of about four water molecules exists at a distance of 28 nm, followed by a second at approximately

45 nm, and beyond 80 nm no shell can be identified. In addition to this short range order, a network of hydrogen bonds exists with a very short lifetime of 10^{-12} to 10^{-13} s .

In sub-cooled, very pure water the nucleation of ice crystals (homogeneous nucleation) starts around -41°C . Normally water contains about 10^6 particles which act as nuclei for crystallization (heterogeneous crystallization). They become more effective as their structure approaches that of ice. Ice crystals exist in nine forms, of which the cubic and hexagonal at under atmospheric pressure. The growth rate of crystals depends on the diffusion of molecules to the nuclei, on finding a suitable place, and on the transportation of the freed energy to the heat sink. With extreme cooling rates (of the order of $10^5^{\circ}\text{C min}^{-1}$), crystallization can be avoided and water solidifies into an amorphous, glass-like phase. **Figure 1** shows that the amorphous phase of ice is only stable below -160°C ; in the range -160°C to -130°C amorphous and cubic phases can exist, and between -130°C and -65°C all the forms can be present, depending on the speed of warming. It is technically impossible to cool pure water quickly enough, to produce glassy ice; even small droplets (1 mm) injected into liquid nitrogen may freeze at a rate less than $10^3^{\circ}\text{C min}^{-1}$. The freezing behaviour of water changes completely if other substances are present in the water, e.g. cryoprotective agents (CPAs). The most widely used CPAs are:

- protein: human serum albumin, gelatin
- amino acids: glycine, arginine, alanine
- alcohols: mannitol, polyethylene glycol (PEG)
- carbohydrates
 - monosaccharides: glucose, fructose
 - disaccharides: lactose, maltose, sucrose, trehalose
 - polysaccharides: dextran, cyclodextrins
- others
 - metals
 - surfactants
 - polymers
 - buffer salts

They all protect in one way or another, alone or in combination, the original quality of the product to be freeze-dried.

As an example of a CPA the influence of glycerol concentration is shown on the right-hand side of **Figure 1**. The temperature of homogenous nucleation

Figure 1 Phase diagram, water-glycerine. On the left-hand side the dependence of the phase transformation time from the ice temperature is shown: at -140°C amorphous ice transforms into cubic ice in approximately 10 min. (From Umrath, W. Kurzbeitrag für die Tagung Raster-Elektronenmikroskopie in Medizin und Biologie, unpublished, Brühl.)

(T_{hn}) can be reduced by about 20°C , the devitrification temperature (T_{g}) can rise by almost 35°C and sub-cooled liquids can exist down to very low temperatures. Polyvinyl pyrrolidone reduces T_{hn} only a few degrees, while T_{g} can be changed by more than 70°C . The freezing of a product is mostly done so quickly that no equilibrium state is reached during the process. The structure of the frozen product depends therefore not only on its components but also very much on the freezing rate and the temperature at the end of the freezing process. Generally speaking, during slow freezing the nuclei have time to grow and the solution in between the ice crystals becomes increasingly concentrated. During quick freezing only small crystals can grow and the remaining solution can become so viscous that the water

molecules cannot diffuse to the crystals and they become part of the solidified liquid (glass) between the ice crystals.

The freeze concentration may, among other effects, change the pH, the water structure around proteins and extract water from cells. The unfrozen water will crystallize during warming when the mobility of the molecules is sufficiently increased. The crystallization can be very abrupt, warm the surroundings, melt it at least partially and destroy the structure. The freezing of a product is as critical as the drying – in some respects even more so. The structure achieved during freezing and solidification determines the main and secondary drying process, the reconstitution of the dried product and its storage capability. Therefore it is mandatory to analyse the

formation of the structure and the factors which influence it.

Methods of Structure Analysis

A number of methods have been described to supply information during freezing. Electrical resistance during cooling and warming (ER) is measured in a test vial at different freezing and warming rates. For a more accurate interpretation of the function $\log(ER) = f(T)$ the first derivative of the plot is calculated as shown in Figure 2. The advantages of the method are: sample size is of the order of a product in

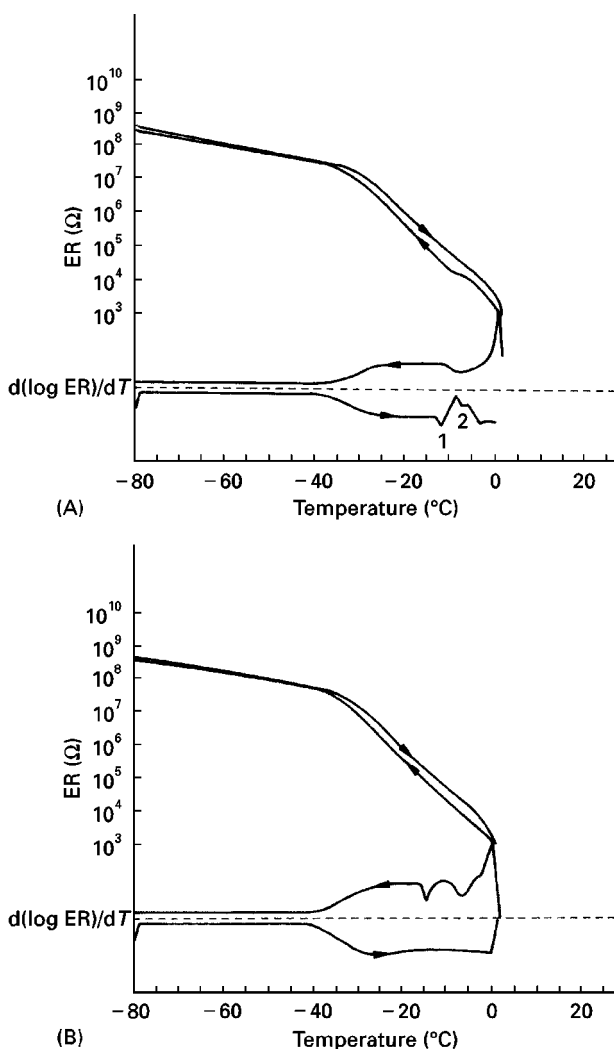

Figure 2 (A) Electrical resistance (ER) of a pharmaceutical product as a function of temperature during cooling at $1^{\circ}\text{C min}^{-1}$ and warming at $3^{\circ}\text{C min}^{-1}$. Heat transfer medium and product are approximately uniformly heated. (B) Measurement of the electrical resistance as in A, but with the wall of the vial insulated by a plastic tape up to the filling height of the product. Heat is therefore mostly removed through the bottom of the vial. (A and B from Willemer, H., Köln, unpublished measurements.)

a vial; it simulates heat transfer from the shelf to the vial/product; and the equipment is relatively inexpensive and easy to operate. The disadvantages are that interpretation needs some experience, the measured data reflect the mobility of ions and the amount of energy used or freed during an event cannot be calculated. In Figure 2A, the heat transfer medium and product are at a similar temperature; in Figure 2B, the wall of the test vial is isolated from the heat transfer medium to simulate the freezing of a product in a vial on the shelf. In Figure 2A, the effect of subcooling during freezing can be seen at about -10°C , but the derivative shows it more clearly between -3°C and -10°C . During warming at event 1 (-12°C) the structure softens, allowing unfrozen water to crystallize, represented by the increase in resistance. In Figure 2B the crystallization energy cannot be quickly removed: freezing occurs in two steps. During warming, events 1 and 2 are not found, all freezable water is crystallized during cooling.

Differential scanning calorimetry (DSC) compares heat flows, one to and from the sample and the other to and from a substance with no transitions in the measuring range. Roos and Karel showed by DSC (Figure 3) the influence of unfrozen water on T_g of fructose (1) and glucose solutions (2). After rapid freezing ($30^{\circ}\text{C min}^{-1}$) to -100°C T_g of fructose and glucose is at -88°C and -84°C respectively; at -48°C and -44°C respectively the unfrozen water crystallizes, followed by the melting of ice. If the products are thermally treated or annealed (after freezing the product is warmed to -48°C for 15 min and then cooled again to -100°C), T_g , called T_g' if all freezable water is frozen, is raised to -58°C and -57°C and no crystallization event is measurable. Time and temperature of annealing must be carefully determined to achieve a certain mobility of the molecules without collapse of the structure (see Figure 9B). The advantages of DSC are the quantitative measurement of the changes in the heat capacity of the sample and the energy freed or used in an event. The disadvantage is the small sample (milligrams), which can behave differently from a product in vials (grams) and the cost of the equipment.

In a cryomicroscope the sample can be optically observed during cooling and warming at different rates. Some models also permit freeze-drying of the sample. Willemer has shown (Figure 4) the structure of a Factor VIII solution during warming after quick freezing. This product must be freeze-dried at a temperature of the sublimation front of the ice (T_{ice}) below -44°C and if annealing is necessary it may be possible at -43°C to -42°C for several minutes but a longer time at -45°C is recommended. The advantage is the visual confirmation of data gained by

Figure 3 Results of annealing (thermal treatment) on the formation of ice in a 60% fructose solution (1) and in a 60% glucose solution (2). Curve A: after cooling at $30^{\circ}\text{C min}^{-1}$ down to -100°C , the DSC plots have been recorded during warming at $5^{\circ}\text{C min}^{-1}$. T_g approximately -85°C and -88°C , respectively, for fructose and glucose. At approximately -48°C and -44°C respectively, ice crystallization starts clearly, followed by the beginning of the melting of ice. (During freezing only a part of the water has been crystallized.) Curve B: after cooling down to -100°C , the product has been warmed at $10^{\circ}\text{C min}^{-1}$ to -48°C , kept for 15 min at this temperature (thermal treatment), cooled down again at $10^{\circ}\text{C min}^{-1}$ to -100°C , and the DSC plot (B) measured during rewarming. During thermal treatment all freezable water is crystallized, and T_g is increased to -58°C and -57°C , respectively. During warming, no crystallization can be detected. (Reproduced with permission from Roos and Karel, 1991.)

other methods, e.g. ER or DSC, and the possibility to analyse the image quantitatively by computer. The disadvantages are high cost and the relatively small region of the sample that can be observed.

Nuclear magnetic resonance (NMR) provides information, among other things about free or bound water (e.g. to protein molecules), the influence of unfrozen water on the collapse temperature and the crystallization of amorphous dry products. Hanafusa has shown by NMR (Figure 5) how the amount of unfrozen (bound) water in a 0.57% ovalbumin solution is reduced by the addition of a 0.01 M solution of sucrose or glycerol. Similar information can be gained for a coffee extract with 25% solids: during freezing and rewarming at -70°C 0.01 g water per gram solid are unfrozen, at -40°C 0.1 g per gram and at -20°C approximately 30%; thereafter the amount increases rapidly. This extract has to be freeze-dried

at a $T_{\text{ico}} < -20^{\circ}\text{C}$, otherwise the structure would collapse. The unique advantage of NMR is the ability to discriminate between free, crystallized and bound water.

More details concerning these methods and additional procedures have been reported by Oetjen.

Freezing Rates

The freezing time can be estimated by an equation developed by Steinbach:

$$t_f = \Delta J / \Delta T \rho_g (\sigma^2 / 2\lambda_g + d / K_{su})$$

where t_f = freezing time; ΔJ = enthalpy difference between the initial freezing point and the final temperature; ΔT = difference of temperature between the freezing point and the cooling medium; d = thickness of the product parallel to the direction of prevailing heat transfer; ρ_g = density of the frozen product; λ_g = thermal conductivity of the frozen product; and K_{su} = surface heat transfer coefficient between cooling medium and the freezing zone.

In this equation K_{su} has to be measured for each type of vial or tray used. The flatness of the bottoms

Figure 4 Photographs taken with a cryomicroscope of Factor VIII solutions at four temperatures. At -40°C the structure is still visible, but is more coarse compared with the appearance at -44°C . At -35°C the structure is collapsed. (Reproduced with permission from Willemer, 1996.)

Figure 5 Unfreezable water (UFW) in a 0.57% ovalbumin solution as a function of the freezing temperature with different CPAs. (Reproduced with permission from Hanafusa, 1992.)

can change K_{su} by a factor of two – if the vials are in trays without machined bottom surfaces by a factor four and more. With K_{su} measured, t_f can be estimated with an error of 10–15%.

Main or Sublimation Drying

The main drying process (MD) has been photographed in a cryomicroscope by Kochs *et al.* as shown in **Figure 6**. The ice crystals grow extremely uniformly using a special freezing method. The ice sublimates and the remaining solids show their original structure after freezing. During sublimation the temperature of the ice at the sublimation front (T_{ice}) has to be kept well below the collapse temperature T_c .

As can be seen in **Figure 6** T_{ice} cannot be measured by a sensor because the ice front travels. If the valve between chamber and condenser (8 in **Figure 11**) is closed for a short time (< 3 s) the water vapour pressure in the chamber rises until the saturation pressure (ρ_g) of the ice front is reached. The rising pressure is measured 100 times per second and the change in the slope (after 2.14 s), if saturation is reached, is determined as 0.286 mbar, corresponding to -32.7°C as shown by Haseley and Oetjen in **Figure 7**. This procedure is called barometric temperature measurement (BTM). It permits checking T_{ice} during MD (e.g. every 10 min). To estimate the main drying time (t_{MD}) the following equation

developed by Steinbach is used:

$$t_{MD} = (\rho_g \zeta_w LS \Delta m d) / T_{tot} \{ (1/K_{tot}) + (d/2 \cdot \lambda_g) + (d/2 LS b/u) \}$$

where ρ_g = density of the frozen product (kg m^{-3}); ζ_w = amount of water (kg kg^{-1}); LS = sublimation energy (2.805 kJ kg^{-1}); T_{tot} = temperature difference ($T_{sh} - T_{ice}$); K_{tot} = total heat transmission coefficient from the shelf to the sublimation front of the ice; λ_g = thermal conductivity of the frozen product; d = thickness of the layer (m); Δm = content of frozen water; and b/μ = permeability ($\text{kg m}^{-1} \text{ h}^{-1} \text{ mbar}^{-1}$) for water vapour through the dried product.

T_{tot} is known, if T_{ice} is measured and K_{tot} has to be measured once for each type of container; one can

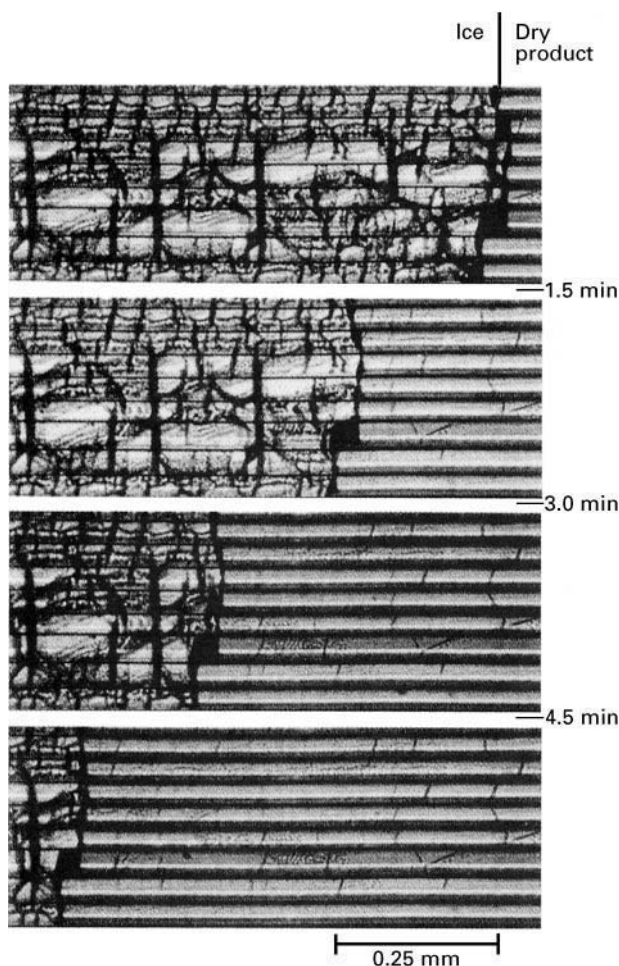

Figure 6 Course of main drying observed using a cryomicroscope, in which freeze-drying is carried out. The hydroxyethyl starch solution is optimally frozen. The dark lines show the form of the sublimated ice crystals. (Reproduced with permission from Kochs *et al.*, 1991.)

Figure 7 Pressure rise as a function of time. 1, Pressure rise in the chamber after the valve is closed; 2, first derivative of 1. The maximum of 2 is reached at 2.14 s; the related equilibrium vapour pressure $p_g = 0.286$ mbar, corresponding to $T_{ice} = -32.7^\circ\text{C}$. (Reproduced with permission from Haseley and Oetjen, 1998.)

expect values between 60 and $120 \text{ kJ m}^{-2} \text{ h}^{-1} \text{ }^\circ\text{C}^{-1}$. K_{tot} is only slightly dependent on the operation pressure up to 0.1 mbar; then it increases up to 1 mbar by a factor of two. λ_g is, in most cases, the figure for pure ice. Δm has to be determined for each product by methods described above. $b/\mu = 1.3 \times 10^{-2} \text{ (kg m}^{-1} \text{ h}^{-1} \text{ mbar}^{-1})$ is an average which is often found in practice, it can vary by a factor of two, but

Figure 8 Density of water vapour flow ($\text{g cm}^{-2} \text{ h}^{-1}$) as function of p_{ch} with jet flow and different l/d as parameter. (Reproduced with permission from Oetjen, 1999.)

the term with b/μ in most freeze-drying processes only has an influence of a few per cent on t_{MD} . The standard deviation of T_{ice} , measurements during MD in the range of -15 to -45°C should be $< 0.5^\circ\text{C}$, if measured automatically. t_{MD} is in most cases governed by the value of T_{tot} and the term $(1/K_{tot})$. The term $(d/2 \cdot \lambda_g)$ is, for d values below 10 mm, of the order of 10% or less of $1/K_{tot}$ growing to approximately 50% at $d = 35$ mm. T_{ice} is the result of a thermodynamic equilibrium between heat transfer to the sublimation front and energy consumption for sublimation. Both depend on several factors, but the heat supply and vapour transport to the condenser are most important during MD. Therefore the operation pressure is a very effective tool to control T_{ice} , if the shelf temperature is kept constant and the condenser temperature is always below a maximum, which depends on the water vapour pressure in the chamber and the design of the plant. By changing the operation pressure, e.g. from 0.1 mbar to 0.8 mbar, T_{ice} can be controlled between -30°C and -20°C . For another product, a different product thickness or a different plant, the pressure range and its controlled range are different, but the dependence is reproducible. Since T_{ice} depends also on the structure of the frozen product it can be used to prove that the structure of products in different runs is homogeneous and sufficiently identical. If the structure contains unfrozen water, T_{ice} data will from time to time jump by 1°C or more (when the water evaporates) and the data will be different for a product frozen at different freezing rates.

At the end of MD the ice is mostly sublimed and the measured T_{ice} decreases below the standard deviation of T_{ice} during MD. This effect can be used to change automatically from main to secondary drying (SD), e.g. if the measured T_{ice} becomes 2 – 3°C smaller than the average during MD. Other criteria are often suggested, such as an increase of product temperature, a decrease in operating pressure or a decrease in partial pressure of water vapour, but it is more difficult to use these other methods quantitatively.

Besides heat transfer, the water vapour transport from the chamber to the condenser is often critical in a freeze-drying process. The length (l) and diameter (d) of the connection between chamber and condenser in a freeze-drying plant as shown in Figure 11 determine the vapour flow, assuming that the other flow resistances in the chamber are relatively small by comparison. The vapour flow can be estimated using the Günther-Jaekel-Oetjen equation. Figure 8 shows that: the vapour flow density decreases in a nonlinear manner with the chamber pressure; the relation of l/d is of increasing importance with decreasing pressure; for example, at 4×10^{-2} mbar the vapour

flow density at $l/d = 5$ is only 30% that at $l/d = 1$. Right-angle bends contribute to the length not only by their physical dimensions but, depending on the design, by a factor of four or more of the measured length. For operation pressures below about 10^{-1} mbar, $l/d > 2.5$ should be avoided.

Secondary or Desorption Drying

Desorption Rates

During secondary drying (SD), water that is removed is more less bound to solid molecules. The amount of water removed is small (e.g. 10% of solids), compared to 10 times the weight of solids during MD. The behaviour of water molecules close to a protein surface has been described by Bellissent-Funel and Teixeira. The water molecules are in a monolayer around the protein with a reduced mobility compared with bulk water.

The desorption of bound water can be measured during SD by measuring the pressure rise in the chamber after closing the valve to the condenser for 60–120 s. The length of time is not critical since the temperature does not change quickly in this phase. The pressure rise ($dp \text{ s}^{-1}$) can be converted into the desorption rate (DR) using:

$$\text{DR} = 2.89 \times 10^2 (V_{\text{ch}}/m_{\text{so}}) (dp/dt)$$

where DR = desorption of water vapour in per cent of solids per hour; V_{ch} = chamber volume (L); dp = pressure rise (mbar); dt = time of dp (s); and m_{so} = mass of solids (g).

The course of DR describes not only the progress of the secondary drying quantitatively, but also reflects the structure of the frozen product as shown by Haseley and Oetjen in Figure 9. In Figure 9A DR data are shown for a 10% mannitol solution frozen in vials on the shelves of the freeze-drying plant at a rate of $0.5\text{--}0.8^\circ\text{C min}^{-1}$. In Figure 9B the same solution in the same vials is frozen in liquid nitrogen and in Figure 9C the solution is frozen in liquid nitrogen but annealed before freeze-drying. From these figures the following conclusions can be drawn. (1) Slow freezing of 10% mannitol solutions results in structures in which the water is bound in several forms. The DR plots as a function of time are not single-valued. (2) Freezing at rates of more than $30^\circ\text{C min}^{-1}$ produces structures with a more uniform desorption behaviour. DR plots show the influence of the operating conditions during MD: (1) run 6 in Figure 9B is collapsed, and the water has dissolved part of the solids, forming a sticky cake. The water

vapour of 378 vials resulted in an unstable T_{ice} , which is $5\text{--}7^\circ\text{C}$ higher than in all other runs. (2) The systematic influence of T_{sh} is shown in Figure 9B and C. (3) The influence of p_c is shown in Figure 9C, and the influence of annealing or low T_{ice} is demonstrated by comparing Figure 9B and C: without annealing, DR plots bend between 3% and 5% per hour; with annealing this effect practically disappears. The exceptions prove the sensitivity of the measurements: run 1 (Figure 9B) is freeze-dried at $T_{\text{ice}} = -36.9^\circ\text{C}$, others at approximately -34.9°C ; run 5 (Figure 9B) is annealed at -40°C but for 8 h; runs 2 and 3 (Figure 9C) are annealed at a temperature 1°C too high and 1.5°C too low for 18 min. Annealing reduces the amount of unfrozen water.

Residual Moisture Content

The integration of DR over time results in the amount of water which can still be desorbed; this is called desorbable water, dW or residual moisture content. In Figure 10 Haseley and Oetjen show the calculated plots from the DR data of Figure 9B and C. From the lower part of Figure 10, it follows that the heat conductivity of the annealed product during SD is almost 100% higher and more uniform than that of the unannealed product. The upper part shows that the correctly treated products and the one dried at a low T_{ice} during MD will dry more quickly than the others.

Storage

The storage capability of a dried product depends generally on its chemical and structural qualities. The complexity of the problem is highlighted, for example, by the storage stability of therapeutic proteins. The degradation of a protein, the irreversible change in primary structure, conformation or state of aggregation in a glassy surrounding depends on the thermodynamic behaviour of the glass as well as on the qualities of the protein produced during freezing and freeze-drying, as shown by Pikal. The storage temperature of such products has to be well below T_g of the dried formulation; nevertheless unfolding or aggregation of unfolded molecules can occur because of poor interaction between the stable glass structure and movements in protein configurations. From this example some simplified guidelines can be proposed. There are no general rules to estimate the maximum storage time at a maximum tolerable temperature – both depend even on small changes in the formulation of a drug or the variations between two types of fruits or the processing methods of extracts (e.g. coffee). In many cases the maximum storage time is

Figure 9 (A) Desorption rate (DR) as a function of time of a 10% mannitol solution frozen on the shelves of the freeze-drying plant at a rate of $0.5\text{--}0.8^{\circ}\text{C min}^{-1}$. In all runs: 300 vials at an operation pressure (p_c) = 0.3 mbar during MD. Runs 1 and 2 at a shelf temperature (T_{sh}) = 20°C ; runs 3 and 4, $T_{sh} = 5^{\circ}\text{C}$. Plot 5 egg albumin and plot 6 saccharose for comparison. (B) DR as in A, but the solution is frozen in liquid nitrogen at a rate between 35°C and $66^{\circ}\text{C min}^{-1}$. During MD all runs at $p_c = 0.15$ mbar, except run 1 = 0.08 mbar and T_{sh} in run 1 = -5°C ; in run 2 = 0°C ; in runs 3–6 = 0°C for the first 11 h, thereafter until end of MD 10°C . In runs 1–5, 126 vials; in run 6, 378 vials. Run 5 intentionally changed from MD to SD 7 h earlier than in runs 3 and 4. (C) DR as in B, but the frozen mannitol was annealed at slightly different temperatures and times:

Run	Annealing temperature ($^{\circ}\text{C}$)	Annealing time (min)
1	– 24	18
2	– 23.5	18
3	– 26	18
4	– 24.5	18
5	– 24	20

All runs at $p_c = 0.15$ mbar, T_{sh} in the first 11 h = 0°C , thereafter 10°C , during SD = 30°C except run 1 $p_c = 0.08$ mbar and $T_{sh} = -5^{\circ}\text{C}$ in the first 11 h. (Reproduced with permission from Haseley and Oetjen, 1999.)

inversely related to the maximum temperature and depends strongly on the residual moisture content ($\pm 1\%$ or less can be decisive). For crystallized products (e.g. antibiotics) the crystal structure must not

change during storage and for glassy products the maximum storage temperature has to be well below T_g (see above). The main difference between the stresses during drying and storage is the length of the

Figure 10 Residual moisture content shown as desorbable water (dW) during secondary drying. Plot 1 = plot 1 in Figure 9B; 2 = 2 (9B); 3 = 3 (9B); 4 = 4 (9B); 9 = 5 (9B); 5 = 2 (9C); 6 = 3 (9C); 7 = 4 (9C); 8 = 1 (9C); 10 = 5 (9C); except run 1, $p_e = 0.08$ mbar and $T_{sh} = -5^\circ\text{C}$ in the first 11 h. (Reproduced with permission from Haseley and Oetjen, 1999.)

effective time: a few hours as opposed to many months up to years.

Relaxation time in molecular configurations may be large compared with the drying cycle, but this may be totally different for the long-term storage time. Besides temperature-induced changes, the residual moisture content (RM) can increase the mobility of molecules and promote chemical reactions. The RM at the end of drying can be as specified; nevertheless moisture can diffuse from the stoppers closing the vials into the product, raising the RM by several per cent during storage. Stoppers and the gas in the container of the product have to be dried carefully. On the other hand, 'the drier the better' is unjustified for many products. The Maillard reaction increases with decreasing water activity ($a_w = p/p_s$, where p = vapour pressure of the product and p_s = saturation vapour pressure) as well as the oxidation of fats. Influenza virus in a freeze-dried formulation shows the

largest decrease in infectivity at 0.4% and 3.2% RM, while at 1.7% it is about 30 times less. Tissue plasminogen activator and human growth factor in certain formulations are optimally stabilized if they are surrounded by a monolayer of water molecules (which may not be distributed evenly).

Freeze-Drying Equipment

Figure 11 shows a freeze-drying plant, designed for maximum current demands. The condenser is cooled by liquid nitrogen controllable between -70°C and -100°C (T_{co}); the brine for the shelves is temperature-controlled (T_{sh}) between $+60^\circ\text{C}$ and -80°C (cooling by liquid nitrogen); the four-stage pump set can reach about 5×10^{-5} mbar (p_e); the vials can be closed shelf by shelf by a hydraulically operated

Figure 11 Freeze-drying plant condenser and shelves cooled with liquid nitrogen. Clean In Place system in chamber and condenser. 1, liquid nitrogen inlet to condenser and heat exchanger; 2 nitrogen outlet from the condenser and heat exchanger; 3, heat exchanger for the brine in the shelves; 4, brine to and from the shelves; 5, pressure plate for closing vials; 6, piston rod with bellows; 7, hydraulic piston for 5 and 6; 8, hydraulically operated valve; 9, hydraulic system; 10 and 13, water and steam inlets; 11, pumping system; 12, water outlet. (Courtesy of Steris GmbH, Hürth, Germany.)

pressure plate; the connection between chamber and condenser is as short as technically possible; the valve between chamber and condenser is operated by a fast hydraulic piston; chamber and condenser can be cleaned by a pressure spray and cleaning system (clean-in-place); chamber, condenser and all components within them can be sterilized by the pressureless Vaporized Hydrogen Peroxide (VHP)[®] process; loading and unloading of the plant is fully automatic; the documentation and control of the total process from loading to freezing, to drying, to closing of the valves, to venting and unloading can be automatic with no thermocouples in the product; this includes the change from MD to SD, the calculation of the moisture content during SD and the termination of the secondary drying at a specified moisture content.

If no extreme temperatures are required, refrigerant compressors can be used for the condenser down to $T_{co} \approx -80^{\circ}\text{C}$ and for the brine down to $T_{sh} \approx -60^{\circ}\text{C}$, and a three-stage pump set is sufficient. If steam sterilization is mandatory, the equipment has to be built for pressures up to 2.5 bar and temperatures up to 125°C .

At the other end of the line of freeze-drying equipment laboratory installations are found, of which a typical example is shown in Figure 12. Usually the product is frozen in vials or trays in a separate freezer

or in the condenser of the plant and the shelves are only heated. The chamber is often a bell jar, $T_{co} \approx -45^{\circ}\text{C}$, $p_e \approx 0.05$ mbar. It is not advisable to use this type of plant as a pilot plant for process development, because the product temperature is not sufficiently uniform and cannot be controlled accurately, especially in the low temperature area.

Regulatory Issues

In the *Validation Documentation Inspection Guide*, US Department of Health and Human Services, Food and Drug Administration, 1993, process validation is defined as follows:

- Establishing documented evidence, which provides a high degree of assurance that a specific process will consistently produce a product meeting its predetermined specifications and quality attributes.
- The *Guide to Inspections of Lyophilization of Parenterals*, published by the US Food and Drug Administration, July 1993, contains among others the chapters 'Lyophilization Cycle and Controls', 'Cycle Validation' and 'Lyophilizer Sterilization/Design'.

(Lyovac® GT 2, Courtesy of Steris GmbH, Hürth, Germany.)

In the European Union, the directive 91/356 EEC provides the principles and guidelines of Good Manufacturing Practice (GMP). In a series of annexes, supplementary guidelines are covered, but up until 1996 only 'Annex 1: Manufacture of Sterile Medical Products' has been revised. In spite of all these guidelines and annexes, Monger summarized the situation for the user of freeze-drying processes and installations as follows: 'It might be expected that some substantial guidance would be provided. Regrettably, this is not so'.

Powell-Evans provided a range of advice on how to 'streamline validation', which he calls 'one of the most time-consuming and costly exercises faced by pharmaceutical manufacturers'. The qualification and validation of freeze-drying installations and processes for the production of pharmaceuticals cannot be summed up in this section. For cosmetic and food products regulatory issues, depending on the country of manufacturing and use, have also to be followed.

Conclusion

Freeze-drying is the most complex and costly conservation process of all drying methods. However, it is the only way for many pharmaceutical products to maintain their original qualities for an acceptable time at readily available temperatures or even at room temperature and above. For food and cosmetic products it provides an opportunity to supply the customers with stable high quality products which can be easily used. For many products, e.g. some antibiotics and some food ingredients, simpler methods of preservation have been developed but in pharmaceuticals there is an increase in the number of products which have to be frozen and freeze-dried at low temperatures using tightly controlled processes. The tendency to automate the whole procedure is promoted by three goals: (1) to have little or no personnel in the sterile areas; (2) to restrict the volume of sterile areas as much as possible, for example by enclosing the whole production line from vial filling to

Figure 13 (See Colour Plate 37). Isolator, Class 100, for filling, transportation and loading of vials into the freeze-drying plant. Decontamination of the isolator and the equipment therein is accomplished by vaporized hydrogen peroxide (VHP). The VHP 100® generator can be seen in the centre in front of the isolator. (Courtesy of Steris GmbH, Hürth, Germany.)

unloading from the chamber in isolators as shown in **Figure 13**; (3) to exclude human error as much as possible and to have each step documented by computer.

To automate an existing process can be more difficult than to develop a new automated process. This is based on several factors. The formulation of the drug has to reflect the automation, e.g. filling and loading can require hours, during which the solution has to be stable, possibly at room temperature. Freezing of the product on the shelves and drying in the chamber have to be executed without temperature sensors in the product; other methods of temperature control have to be used, tested and installed. Criteria have to be defined for the automatic change from main to secondary drying. Automatic termination of the secondary drying has to be effected when certain measurable events are accomplished. Besides these main points several others have to be evaluated. More accurate and independent sensor systems will influence freezing and drying procedures. The required data processing and the actuators to fulfil the commands are available today.

See Colour Plate 37.

Introduction

Engineers and scientists frequently have the problem of separating a mixture into its components or need to purify a specific product. To solve the problem they usually apply a heuristic procedure, such as the following McMaster five-stage method:

1. Identify and define the problem.
2. Propose and develop several alternatives to solve the problem.
3. Based on available resources, choose one or two of the best alternatives.
4. Work on the chosen alternatives in greater detail and compare them before selecting the most appropriate solution.
5. Evaluate and decide if the problem has been solved.

Let us assume that, for step 1, the problem is identified as the recovery of one or more organic compounds from a mixture, or the purification of a specific chemical.

In order to apply the second step, the differences in physical properties are taken into account. Sometimes the physical properties of the components are very different, so that, if two phases already exist in the mixture, mechanical separations such as filtration or decanting may then be used. But more often the components of the mixture form a single phase and other differences in physical properties need to be found.

When a homogeneous mixture is formed with components of different vapour pressure or different boiling points, then distillation may be one of the several alternatives proposed in step 2. As will be seen later, the relative volatility (α) of a mixture is:

$$\alpha_{i,j} = \frac{K_i}{K_j} = \frac{y_i/x_i}{y_j/x_j} \approx \frac{p_i^0 \gamma_i \phi_j}{p_j^0 \gamma_j \phi_i} \quad [1]$$

where K_i and K_j are the equilibrium constant for components i and j respectively. These K values provide for each component a linear relationship for the

mole fraction in the gas phase and the mole fraction of the same component in the liquid phase. Eqn [1] shows that the equilibrium constant and relative volatility depend on the ratios of vapour pressure, liquid-phase activity coefficients (γ) and vapour-phase fugacities (ϕ).

The relative volatility α is a measure of the ease of the separation.

- If $\alpha = 1.0$ the separation is not possible by distillation.
- If $\alpha \geq 1.2$, distillation will probably be a good alternative, and should be chosen as the next step.

In step 4, the distillation system should be designed. The design and analysis of these columns operating at high and low pressure form the core of this manuscript and are presented in the next sections.

Finally, in step 5, the scientist or engineer debates whether the problem have been solved satisfactorily. If this is the case, the problem is finished; if not, it is necessary to go back and start again.

Distillation

Distillation is based on diffusion of one or more components through a mixture operating at a temperature, pressure and composition that assures the presence of liquid and vapour phases. In distillation, the mass transfer is due to a concentration difference moving from a place of high concentration to one of low concentration; it is not bulk movement as a result of a pressure gradient, like pumping liquid through a pipe.

Relative Volatility

The key separation factor in distillation is the relative volatility, defined by eqn [1]. As the value of relative volatility increases, the easier it is for components to be separated by distillation.

The number or theoretical stages required to separate two species to a desired degree is strongly dependent on the value of α .

The variation of this parameter with pressure is shown in **Figure 1** for the system ethane–propane. As seen, α is greater at low pressure than at high pressure. Therefore, at low pressure (e.g. 1 atm), for

Figure 1 Variation of relative volatility with pressure.

a specified separation, the number of theoretical stages is less than at high pressure (e.g. 10 atm). In this case, why not use low pressure for this separation? As will be seen later, the temperature at the top and bottom of the column plays an important role in this decision. At low pressure (0.05 atm) top temperature -130°C , while at high pressure (30 atm) top temperature is 10°C . Therefore, distillation at high pressure is used since it is much easier and more economical to reach 10°C than -130°C .

Classification, Equipment and Design of Distillation Columns

Distillation is the separation process most used in the chemical and petrochemical industry; as shown in Table 1, its operation is classified into several forms.

Most of the time, distillation is carried out in vertical columns or towers (like the packed column shown in Figure 2) where the liquid descends while the vapour ascends to the top of the column. The vapour left at the top of the tower is condensed and at least a fraction is returned back to the top of the tower as liquid reflux. Part of the liquid leaving the bottom of the column is vaporized in a reboiler and returned to the column as boil-up.

How the distillation equipment operates and how it is calculated has been modified over the years. Figure 3 shows some developments related to distillation.

The design or sizing of distillation equipment requires the calculation of diameter and height of the column. Diameter depends on volumetric flow rates of liquid and vapour inside the column, and these are functions of the total amount of the mixture feed to the column and the reflux or boil-up ratios. The desired purity of the components at the top and bottom of the tower dictates the height of the column. First, the theoretical or ideal plates are calculated, then efficiency is estimated to convert from ideal to real stages. By specifying the distance between plates (30–60 cm), and providing space for about four plates at the top of the column and six for the bottom for disengagement of the phases, the total height of the shell is determined. Figure 4 shows a block diagram for a typical design of a distillation column.

Distillation at high and low pressures involves special characteristics, summarized in Table 2.

With Internal Devices of Distillation Columns

There are three types of internal devices which provide the intimate contact between phases in a distillation column. These are tray, random packing and structured packing.

Table 1 Different classifications of distillation equipment or operation

Amount of compound to be separated	Solute recovery Fractionation
Mode of operation	Steady-state Unsteady-state Batch Semibatch Start and shut-down Stagewise contact Continuous contact
Mixing between phases	None Plates Bubble cups Sieve Valve
Internal device used	Packing Random Structured
System characteristics	Flash Fractionation Azeotropic Extractive
Operating pressure	Low High vacuum Medium vacuum Low vacuum Medium High

Figure 2 Distillation column equipped with structured packing.

Each has advantages and disadvantages. Trays have been used for many years. Random packings have also been used over three generations of design. Structured packings have replaced trays, especially in applications at low and atmospheric pressures. At high pressure, trays perform better than packings.

For any application one must determine whether tray or packing is the most appropriate. The following factors are an indication of when trays or packings are favoured.

Factors favouring trays

- High liquid rate (this occurs when high column pressures are involved);
- large diameter (packing prone to maldistribution);
- complex columns with multiple feed/take-offs;
- feed composition variation;
- scale-up less risky;
- columns equipped with tray weigh less than those equipped with some packings.

Factors favouring packings

- vacuum conditions;
- low pressure drop required;
- in smaller diameter columns (where trays are more difficult to install, diameters 0.6–0.9 m or less);
- corrosive system (more construction materials available);
- foaming;
- low liquid hold-up.

High Pressure Distillation

As seen from Table 3, distillation at high pressure cover a wide range of applications that have some of the following characteristics:

1. The compounds have low molecular weight (like C_2 , C_3 , C_4 hydrocarbons).
2. Cooling water can be used in the condenser.
3. A change in pressure could change the azeotropic point by more than 10% (in mole fraction).
4. Energy is integrated between condensers and reboilers of different columns.

Sometimes the increase in pressure is limited by the heat sensitivity of the bottom product (it could polymerize or degrade) or by its critical temperature or pressure. As is known, at the critical conditions only one phase exists. If the mixture reaches this point two phases cannot exist anymore and therefore separation is not possible. It is necessary, therefore, to be careful when one is thinking of the operating column pressure.

The upper pressure could be limited by economical conditions. If water is used as cooling medium at the top, the pressure required may be too high and therefore it would be necessary to use a refrigerant. Some authors recommend a upper pressure value of 1.48 MPa using a total condensation with water, 2.52 MPa using partial condensation with water, and if the pressure required is higher than this value it is recommended to fix the top pressure at 2.86 MPa using partial condensation with a refrigerant.

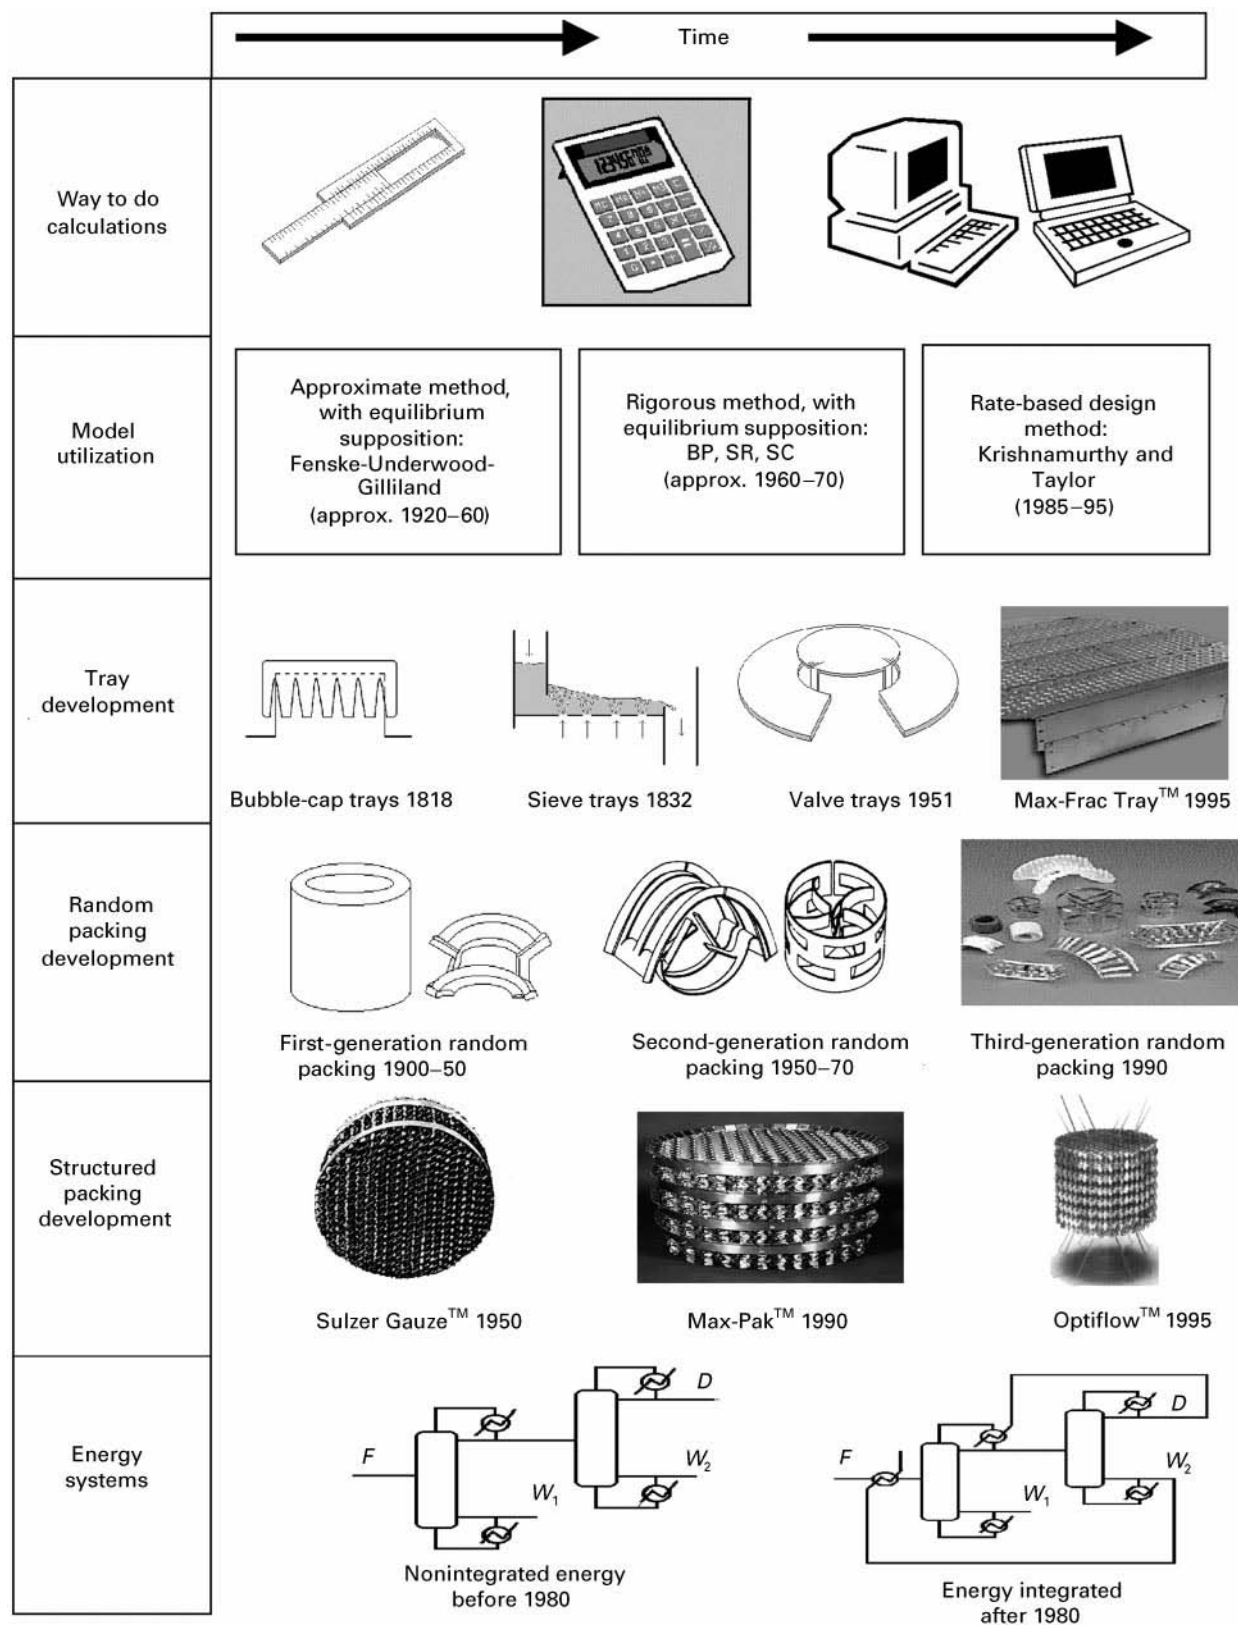

Figure 3 Paradigm shifts related to distillation. (With permission from Chemical Engineering Process (1972) 68 (8): 16).

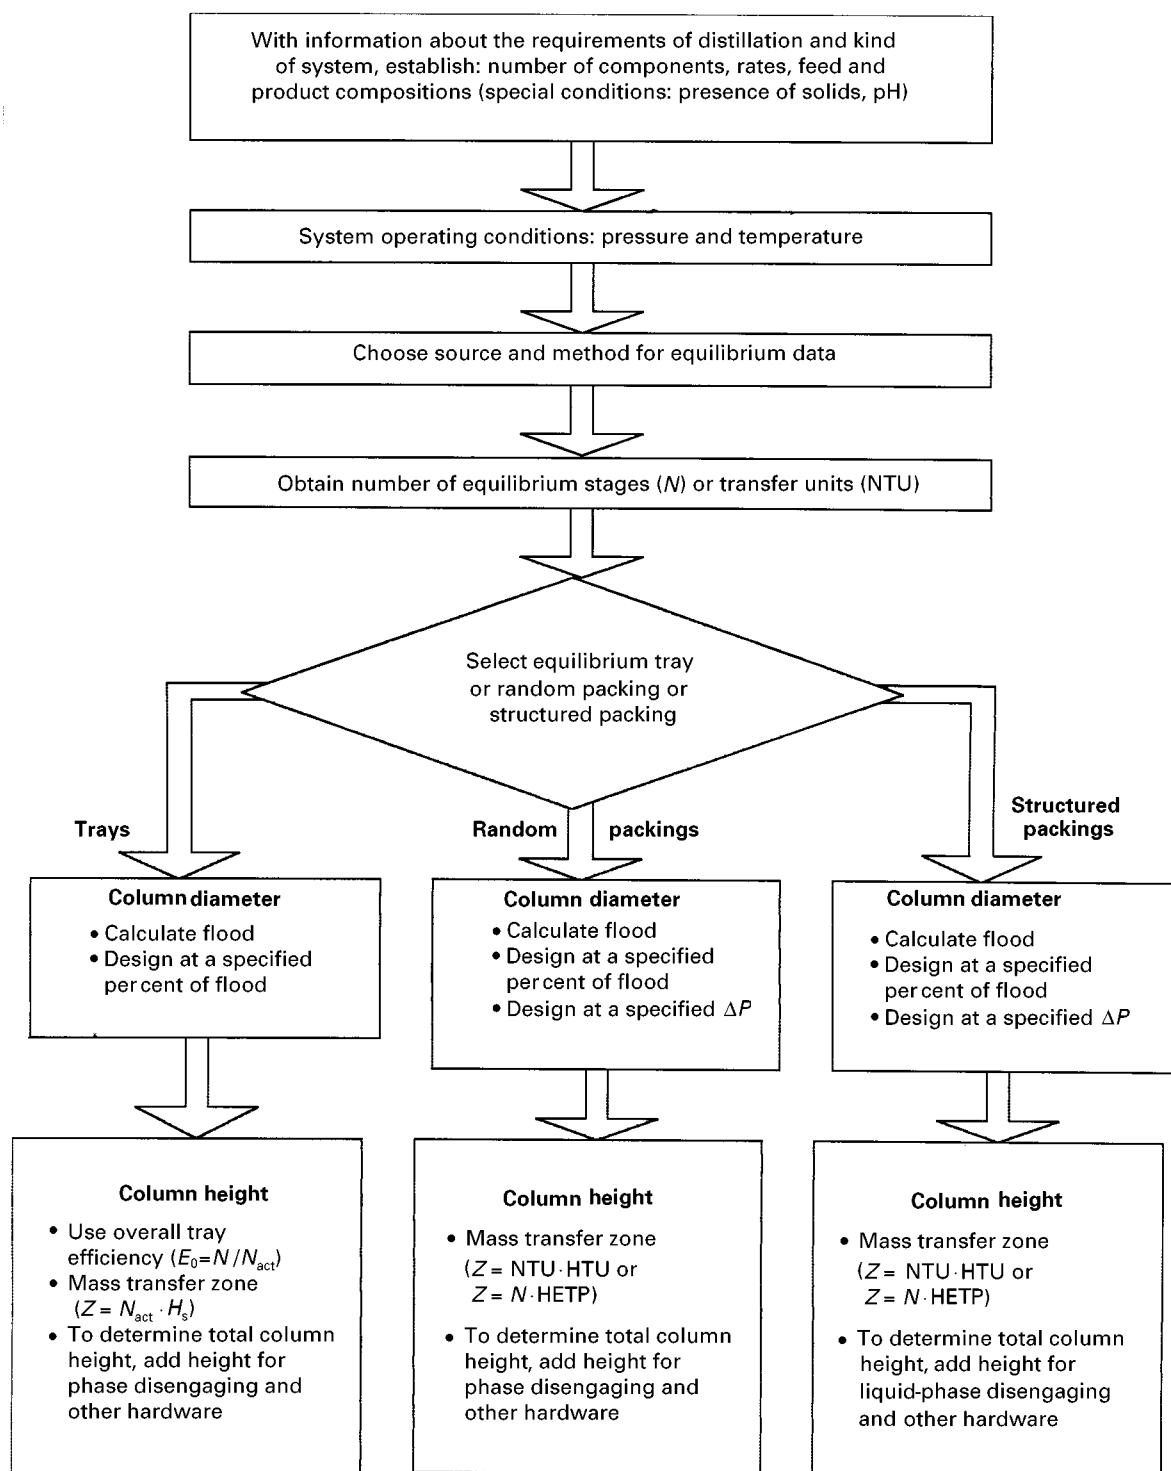

Figure 4 Procedure for designing a distillation column.

The upper pressure also could be limited by cost. If pressure is increased above 1 MPa, all equipment costs begin to go up. For instance, a stainless steel column with sieve trays could double in cost when the pressure is raised from 0.1 to 3 MPa. A similar rela-

tionship exists for other equipment and materials of construction.

Some specific applications of high pressure distillation are given in Table 3. Most applications are in the petrochemical industry, but another very important

Table 2 Characteristics of high and low distillation operation

Feature	Low pressure	High pressure
When is it used?	Products sensitive to temperature (thermal degradation) Avoid using high pressure steam Break azeotropes and allow separation of the system; also when a significant change occurs at the azeotropic composition (about 5%) with change in pressure When trains of distillations columns with energy integration are desired allow energy of overhead vapour partially to vaporize the bottom of the other column)	Gas feeds (C ₂ /C ₃ /C ₄ separation, air separation and ammonia recovery) Allow water to be used in the condenser
Liquid density	High molecular weight of components No significant change	Low molecular weight of components Decreases slowly when pressure increases
Vapour density	Low; decreases if pressure decreases	Increases quickly if pressure increases
Liquid diffusivity	Low; increases slowly if pressure increases	Increases quickly if pressure increases
Vapour diffusivity	High; decreases if pressure increases	Low; decreases quickly if pressure increases
Liquid viscosity	High; decreases quickly if pressure increases	Low; decreases quickly if pressure increases
Vapour viscosity	High; no significant change at low or high pressure	High; no significant change at low or high pressure
Relative volatility	Increases if pressure decreases	Decreases if pressure increases
Flow parameter $F_p = \frac{L}{G} \sqrt{\frac{\rho_G}{\rho_L}}$	< 0.1	> 0.3

application is cryogenic air separation. This is based on a low and high pressure distillation column. The reboiler of the low pressure upper column (0.13 MPa) cools the condenser of the high pressure lower column (0.60 MPa). As can be seen, the high pressure column does not have a high pressure value but neither is it at atmospheric pressure.

The Further Reading section cites a good report on high pressure distillation by Brierley which gives some tips on improving an existing column and de-

signing a new one. High pressure distillation begins about 1 MPa, where liquid density, liquid viscosity and surface tension are unusually low, while vapour density is high. Trays are recommended as internal devices, especially above 2 MPa; below this value, trays and packings must be evaluated. Many problems in high pressure distillation could be avoided with an appropriate design. Available design methods for low pressure can be applied to high pressure but with some corrections, specifically in downcomer design because this is where liquid flooding usually starts in high pressure distillation, while in low pressure, the bottleneck is the vapour flow through the active area. Downcomer design should consider both downcomer back-up and downcomer velocity.

Three flow regimes may exist in industrial columns: spray, froth and emulsion (see Further Reading). In high pressure distillation, tray operation is usually in the emulsion regime, where liquid loads are high and vapour velocities comparatively low. However, in small diameter column (less than 1.5 m) at low liquid loads or at the low end of the high pressure range (about 1 MPa), froth and spray regimes can be found. In the spray regime, flooding is caused by excessive entrainment of liquid from the active area to the tray above. It increases the tray pressure drop and the entrained liquid recirculates to the tray below. The larger liquid load in the downcomer and the increased tray pressure drop together cause the downcomer to overfill, so that the tray floods. In the emulsion

Table 3 Specific applications of high pressure distillation

Application	Pressure Range
Ethylene plant	
Demethanizer	32 MPa
Deethanizer	27 MPa
C-2 splitter	16 MPa
Depropanizer	19 MPa
Debutanizer	5 MPa
Dimethyl ether (DME) production (via the dehydration of methanol)	
DME column	1.60 MPa
Water column	0.75 MPa
Production of heptenes from propylene and butenes:	
C ₃ + C ₃ = /mixture separation	0.60 MPa
Miscellaneous hydrocarbons	
Propylene/propane separation	2.1 MPa
Cryogenic air separation	
Lower column	0.6 MPa

regime, there is little entrainment of liquid by the vapour; instead, the high liquid load causes the downcomer to overflow and the tray to flood. In the froth regime, which is between the spray and the emulsion ones, flooding may be by either mechanism, depending on tray spacing and the particular combination of vapour and liquid loads.

A new model for the design or analysis of sieve tray columns has been developed at the University of Texas at Austin, in its Separation Research Program. This model applies to both low and high pressure columns. The model was adjusted with a wide experimental database from the open literature and also from the Separation Research Program facilities.

The equipment used to perform distillation at high pressure is basically the same as that used for close to atmospheric pressure, but the following special considerations should be taken into account.

1. The physical properties move in the direction indicated in Table 2 (liquid density, liquid viscosity and surface tension are low and vapour density is high).
2. The thickness of the shell and column peripheral equipment must be greater.
3. The advantage in capacity and/or efficiency of structured packing over random packing and plates decreases as the pressure increases.
4. At very high pressure the efficiency of distillation decreases, due to back-mixing.
5. At very high pressure the use of plates (standard and high capacity) is more reliable than packing.

The design equations for packed columns are basically the same, with one possible correction to the height of a transfer unit (HTU) value, to take into account the deviation from plug flow:

$$HTU_{\text{total}} = HTU_{\text{plug flow}} + HTU_{\text{back-mixing}} \quad [2]$$

Remember that at high pressure the density of gases increases by several orders of magnitude; the opposite is true for the diffusivity of the gas phase, and the surface tension decreases to very low values.

Low Pressure Distillation

Modern society is becoming ever more demanding in the quality of the products it uses and for health and environmental reasons a better removal of some components is required. This better purification of many products sometimes requires operating at very low pressure. Fortunately, the development of industrial

equipment to obtain better and lower vacuum has been maintained. The cost of carrying out these operations is of course more expensive than at around atmospheric pressure. The increase in cost is inversely proportional to the absolute operating pressure.

Distillation at low pressure is used for special cases with one or more of the following characteristics:

1. heat sensitive products;
2. liquid feeds or liquid residue with high viscosity;
3. liquids with fouling and/or foaming tendencies;
4. low operating pressure (medium and high vacuum);
5. low residence time.

The applications may be classified into four groups:

- distillation or evaporation of sensitive organic chemicals;
- concentration of foods, chemicals, polymers and biological compounds;
- recovery of organic solvents;
- desolventing, devolatilization and finishing of polymer solutions.

Table 4 shows the levels of vacuum used and also lists representative equipment. Some advantages of vacuum and molecular distillation are:

- low residence time;
- high selectivity due to the higher values for relative volatility;
- cheaper heating requirements.

Some of these special kinds of distillation are discussed below.

Agitated Thin-film or Wiped-film Evaporators (WFE) and Short Path Distillation Equipment

For medium vacuum distillation, thin-film evaporators are used with or without agitation, but evaporators with scraping blades provide better performance and flexibility. Where there are heat-sensitive substances, thermal decomposition may occur during evaporation. Decomposition increases exponentially with temperature and linearly with duration of thermal load. A gentle distillation method therefore reduces the evaporation temperature and the residence times at high temperature.

Since the evaporation temperature depends on pressure, evaporation is performed under vacuum at considerably lower temperatures. If, in addition to applying vacuum, the thickness of the material on the

Table 4 Classification of low pressure distillation

	Approximate pressure	Typical equipment
Low vacuum	760 to 1 Torr (1000 to 1.315789 mbar)	Vacuum column internals Plates Random packing Structured packings
Medium vacuum	1 to 10^{-3} Torr (1.315789 to 0.013157 mbar)	Thin-film evaporators Agitated thin-film evaporators
High vacuum	10^{-3} to 10^{-7} Torr (0.013157 to 0.0000013 mbar)	Short path distillation Molecular distillation Rotary stills Falling-film stills Wiped-film stills Centrifugal stills

Adapted with permission from Eckles AJ (1997) Difficult to process? Vacuum it! *Chemical Engineering* 94–100.

evaporator wall is reduced, lower evaporation temperature and shorter residence times can be achieved.

Most WFE are vertical cylinders where the feed material is distributed to the inner surface; as the liquid flows downward, axially arranged blades or roller wipers distribute the liquid as a thin film which is constantly mixed. In Figures 5 and 6, two types of WFE are shown. Figure 5 illustrates a WFE with rotating blades, while Figure 6 shows a unit with roller wipers and condenser. The last feature is a distinct characteristic of short path evaporators and molecular distillation stills. These types of equipment

operate at the lowest pressure and provide the lowest pressure drop.

The double-walled evaporator jacket is heated continuously with a heating medium. A vacuum system (often a combination of several individual pumps) reduces the pressure in the distillation chamber.

Figure 5 Agitated thin- or wiped-film evaporator (WFE) with rigid blade rotor.

Figure 6 Wiped-film evaporator or short-path distillation equipment, with roller wiper system.

Depending on the temperature and the pressure in the distillation chamber, vapours leave through the vapour discharge and travel to an external condenser. Involatile substances are discharged at the lower end of the evaporator.

The cylindrical evaporation chamber is externally heated with hot pressurized water, steam or heat transfer oils.

Essential parts of a WFE are the rotating blades or roller wiper system, which are axially arranged in the evaporator. The blades (or roller wiper system) influence the following aspects:

- Film thickness: the components to be evaporated are more easily separated from a thin film.
- Uniformity of distribution: uniform distribution of the feed material on the evaporator surface promotes excellent heat transfer and avoids overheating.
- Mixing of the film: optimal mixing within the liquid film increases the complete separation of the components, thus enhancing evaporation.
- Residence time: if gentle distillation is required, heat-sensitive materials can be heated in the evaporator for only a short period of time. With a well-constructed blade or wiper system, the residence time can be considerably reduced.

Thin-film evaporators can be totally vacuum-sealed, thus avoiding any oxidation of product caused by penetration of air.

Discharge of the distillate vapours takes place above the feed nozzle. This is why undistilled liquid droplets, which may occur during flash evaporation, are trapped in the head of the evaporator and then flow back to the evaporator surface.

McKenna (see Further Reading) provides equations to design or analyse operation of a WFE. Some of the important equations to calculate the final concentration C_F of the residual liquid are:

$$C_F = \frac{C_0 - C^*}{(1 + \alpha)^{n_{\text{total}}}} + C^* \quad [3]$$

$$\alpha_n = 2\pi^{1.5} \text{Dif}^{0.5} \frac{w^{0.5} d_e^2 \tan \phi}{QN_b^{0.5}} \times \left[1 + \frac{2N_b Q^{0.5}}{\pi^{2.5} d_e^2 w^{0.5} \tan \phi} \left(\frac{\pi d_e}{N_b} - l_b \sin \phi \right)^{0.5} \right] \quad [4]$$

$$n_{\text{tot}} = \frac{H_e d_e}{d_e H_s} = \frac{H_e N_b}{d_e \pi \tan \phi} \quad [5]$$

Advantages of the process of WFE and short path distillation Thin-film evaporators offer a number of advantages. If higher operating pressure and temperature are required for economic reasons, thermally sensitive materials can still be processed because of the short residence times utilized in WFE equipment.

The thin liquid film and turbulent mixing of the film result in very quick attainment of equilibrium. This is especially important if a complete separation of a low boiling, volatile component out of the residue is required. This is why thin-film evaporators are successfully used as reboilers for rectification columns.

Thin-film evaporators are excellent degassers. If, for example, small quantities of a volatile component have to be removed down to only a few p.p.m., the evaporation capacity is not very important. The main goal in this case is to transfer the portions to be separated as completely as possible to the surface of the film. The transport is achieved by the roller wiper or blade system.

Molecular Distillation

Molecular distillation may be considered as a special version of evaporative distillation in which the liquid is evaporated without boiling, but in such circumstances that the evaporating molecules reach the condenser surface without obstruction. Three conditions for molecular distillation are:

1. Pressure must be lower than 0.001 mmHg. This low pressure is required to ensure that the molecules do not collide with each other.
2. The distance between evaporation and condensation surfaces is of the same order of magnitude as the mean free path of the molecules and the free motion of the molecule is not mechanically hindered.
3. The temperature of the condenser surface should be between 50 and 100°C lower than that of the evaporation surface to prevent re-evaporation of molecules.

The mean free path λ is given by:

$$\lambda = \frac{1}{\sqrt{2}\pi\sigma^2 N} \quad [6]$$

where σ is the diameter of the molecule in centimetres and N is the number of molecules in 1 cm³. By reducing the pressure to very low values, N decreases, giving values for λ of 1–3 cm, in the range of the distance between evaporator and condenser surface.

In molecular distillation the maximum or theoretical rate of evaporation was proposed by Langmuir in 1916:

$$W_e = 0.0583 P_{\text{mm}} \sqrt{\frac{M}{T}} \quad [7]$$

where M is the molecular mass and T is the absolute temperature.

The relative volatility is given by:

$$\alpha_{1,2} = \frac{p_1^0 \gamma_1 \sqrt{M_2}}{p_2^0 \gamma_2 \sqrt{M_1}} \quad [8]$$

From these two equations it may be seen that molecular weight of the compounds involved is an important consideration.

Equipment for molecular distillation and medium vacuum is expensive, but it is economically justified for the separation of high value products such as vitamins, fats, essential oils and hormone concentration.

Typical unit operations and applications for medium and high vacuum using WFE, short path

Table 5 Specific applications of low pressure distillation

<i>Unit operations where wiped-film evaporators (WFE) are used</i>	
Evaporation	Drying
Concentration	Degassing
Distillation	Reactions
Stripping	Deodorizing
Heating	

<i>Distillation</i>	<i>Concentration</i>
<i>Application of WFE for distillation and concentration at pressure of 1–1000 mbar</i>	
Acrylonitrile	Extract solutions
Essential oils	Insulin
Amines caprolactam	Peroxides
Quinoline derivatives	Phospholipids
Diocetyl phthalate	Pyrethrum
<i>WFE for distillation and concentration of viscous products</i>	
Fatty alcohols	Resins
Waxes	Honey
	Glue
	Polymers
	Lubricant oils
	Silicone fluids
<i>WFE for distillation and concentration of products liable to encrust the heated surface</i>	
Used oils	Contaminated effluents
Solvents containing impurities	Residue products from rectification and evaporation plants

equipment or molecular distillation are shown in Table 5.

Technologies to Improve Distillation Processes

There are several ways of improving the separation of mixtures into the desired products. Some of these combine distillation with other processes (like adsorption, stripping, pervaporation, reverse osmosis, membranes, etc.). Others are improvements to the internal devices (such as high efficiency trays or high efficiency packings). There are also the so-called enhanced distillation methods (like extractive distillation, homogeneous and heterogeneous azeotropic distillation, reactive distillation, heat integration, high gravity distillation, spinning cone distillation, mechanical vapour recompression, and pressure swing distillation). Further information about these technologies can be found in the texts cited in the Further Reading section.

Conclusion

In the 21st century, distillation at high, medium and low pressure, will continue to be a much used method for the separation of components from homogeneous mixtures.

Introduction

Distillation is one of the oldest and most widely studied unit operations in chemical engineering. It is familiar as a separation technique to chemical, process and petroleum engineers and to chemists. The common techniques, design methods and numerous applications have been extensively documented in monographs and in the journal literature (and conference proceedings) over many decades. Specialist texts and more general handbooks should be familiar to those working in related fields, therefore these standard sources are not documented here. The importance of distillation and its future directions have been discussed by Kunesh *et al.* (1995) and by Porter (1995) (see Further Reading). This article presents a state-of-the-art overview of distillation by concentrating on recent advances and possible future developments.

Sources of Information and Data

For a subject as old as distillation, and with such a wide range of applications, there is an extensive collection of published information. With the advent of electronic databases and online web-based resources it has become much easier to perform literature searches on particular topics and to keep abreast of the current literature and recent developments. For this reason an extensive reference list to journal articles is not provided in the Further Reading at the end of this article. Selected papers are included that can be used to locate related references. Author or subject searches of the journal literature (from 1956 to the present, with six-monthly updates) can easily be performed by using the **CHERUB™** *Chemical Engineering Database* (compiled by M. S. Ray) which is included on the *Engineering & Applied Science CD-Rom Database*. The ability to easily search the chemical engineering literature is a recent development, and is an important advantage for distillation re-

searchers. Another useful reference source is a series of annual update bibliographic papers on 'Equilibrium-staged Separations' (e.g. *Separation Science and Technology* 32(18): 3067–3083, 1997). Patent searches can also be performed on the web, e.g. www.ibm.com/patents, and www.uspto.gov (the website of the US Patent & Trademark Office). Several handbooks and monographs (and CD-ROMs) containing property data useful for distillation systems have also been compiled, e.g. C. L. Yaws (transport properties data and thermodynamic diagrams); J. Gmehling and co-workers (including VLE data, heats of mixing, azeotropic data); and the *American Institute of Chemical Engineers' Design Institute for Physical Property Data (DIPPR)* publications.

Prediction of Vapour–Liquid Equilibria (VLE) Data

Significant advances in the interpretation and prediction of vapour–liquid equilibria (VLE) data have been made since the 1970s. These advances developed from the publication of a range of equations of state (EOS) based upon the application of traditional thermodynamic principles and relationships. The EOSs provide interpretation or evaluation of available experimental VLE data. The Wilson model (1964) is probably the most popular for dealing with liquid-phase activity coefficients because it has only two adjustable parameters, and it works well for both binary and multicomponent systems. The prediction of nonidealities in binary mixtures using the UNIQUAC model (1975) is rather more complex. Subsequent and related studies led to the development and use of the Group Contribution Methods such as ASOG and UNIFAC for the prediction of VLE data. The latter is widely used when actual system data are not available, provided that an approximate nonideality correction is acceptable. New methods are being developed and probably the one showing most promise and of general applicability is known as: A Generalized Approach to Phase Equilibria (AGAPE, 1995).

There are many EOS models described in the literature but only a few have wide use for engineering

applications. The Redlich–Kwong equation (1949) and its modification by Soave (1972), and the Peng–Robinson equations (1976) have broad general application for nonpolar components and are the most widely used, especially in the refining and gas processing industries. For highly nonideal components, use of the EOS requires an appropriate mixing rule. The alternative approach is direct application of liquid activity model parameters in the EOS. A collection of papers relating to the development of the Peng–Robinson EOS over 20 years was published in 1998 (*Industrial and Engineering Chemistry Research* 37(5): 1579–1706).

The availability of commercial software packages, e.g. flowsheeting design packages such as HYSYSTM and PRO/IITM (see below), have made the prediction and evaluation of equilibrium data quicker and easier. These packages were generally developed for use by the oil and gas industry and refining companies, and they include extensive VLE prediction equations integrated within the design methods. Some of these prediction methods have been developed specifically for use with common petroleum systems (e.g. Chao-Seader; Grayson-Streed).

Applications of the Design Methods
